Dr. T.J. Greer, MDPhD

This anthological textbook is composed of over 50 scholarly articles focused on topics and subtopics in genomic medicine. However, it begins with a brief synopsis of genetics, medicine, and genomic medicine. Please enjoy— Dr. T.J. Greer, MD/PhD, Harvard University

Introduction

DNA (deoxyribonucleic acid) is a complex molecule that contains all of the information necessary to build and maintain an organism. All living things have DNA within their cells. In fact, nearly every cell in a multicellular organism possesses the full set of DNA required for that organism. However, DNA does more than just specify the structure and function of living things — it also serves as the primary unit of heredity in organisms of all types. In other words, whenever organisms reproduce, a portion of their DNA is passed along to their offspring. This transmission of all or part of an organism's DNA helps ensure a certain level of continuity from one generation to the next, while still allowing for slight changes that contribute to the diversity of life (Nature Education, 2014). Moving on, medicine is a discipline centered on health and healing. It includes nurses, doctors, and various specialists. It covers diagnosis, treatment, and prevention of disease, medical research, and many other aspects of health. Medicine aims to promote and maintain health and wellbeing. Standard medicine is often called allopathic medicine. It involves the use of drugs or surgery, often supported by counseling and lifestyle measures. Alternative and complementary types of medicine include acupuncture, homeopathy, herbal medicine, art therapy, traditional Chinese medicine, and many more (Biggers, 2018). Combining these concepts, we see that genomic medicine is a discipline that involves using a patient’s genomic information as part of their clinical care. Other similar terms include individualized medicine, personalized medicine and precision medicine. For some conditions, genomic information can be used to help diagnose disease, predict outcomes and guide the appropriate treatment.

Now, let’s look at the central dogma of biology. DNA is the body’s blueprint. RNA is a cheaper copy of the DNA blueprint. Amino acids are tools, and proteins are the materials used to build the final products, products like cell walls, tissues, organelles, etc. (DNA replication): this process occurs during cell divisions and allows genetic information to pass from a mother to a daughter cell. DNA is copied to RNA (RNA transcription): this is the first step of the gene expression process. mRNA molecules are responsible for the transfer of the genetic information from the nucleus (where the information is stored) to the cytoplasm (where protein synthesis occurs). RNA is then used as a template to synthetize proteins (protein translation): this is the final step of the gene expression process. The ribosome, a specialized complex that "reads" the sequence of mRNA nucleotides, interacts with the mRNA. Each sequence of three nucleotides, called a codon, typically codes for one specific amino acid. The protein is assembled one amino acid at a time by tRNA. Protein assembly continues until the ribosome encounters a “stop” codon–a sequence of three nucleotides that does not code for an amino acid (Martinez, 2022). With this foundation laid, let’s further contextualize medical genomics. Medicine’s history is full of moments when one discovery suddenly redefined what was possible. From antibiotics to artificial intelligence, these breakthroughs haven't just changed how we treat disease—they've completely reshaped how we understand the human body.

Next, let's look at ten of the most transformative innovations in medicine, followed by a few modern breakthroughs that continue to contextualize genomic medicine. First, few discoveries have saved as many lives as antibiotics. When Alexander Fleming discovered penicillin in 1928, he couldn't have known it would change the course of medical history (Fleming, 1929). Before antibiotics, infections like pneumonia or sepsis were often fatal. Mass production during World War II made penicillin widely available, saving thousands of soldiers from infected wounds (Lax, 2004). Later antibiotics like streptomycin and tetracycline expanded the fight against tuberculosis and other diseases (Waksman, 1953). Although antibiotic resistance is now a growing threat (Ventola, 2015), the discovery remains one of humanity's greatest scientific victories.

Next, vaccinations transformed medicine from reactive to preventive care. Edward Jenner's smallpox vaccine in 1796 proved that exposure to a harmless form of a virus could protect against deadly infection (Jenner, 1798). The result? Smallpox became the first human disease ever eradicated in 1980 (Fenner et al., 1988). Since then, vaccines have nearly eliminated polio and drastically reduced measles, diphtheria, and tetanus (Plotkin, 2014). The success of the COVID-19 mRNA vaccines also showed how rapidly biotechnology can respond to new threats (Krammer, 2020). Vaccines continue to be the backbone of global public health.

Moving on, before anesthesia, surgery was brutal and often deadly. That changed in 1846 when dentist William Morton publicly demonstrated the use of ether at Massachusetts General Hospital (Snow, 1847). For the first time, patients could undergo surgery without agony. The development of chloroform and later safer inhalation agents made complex procedures possible and humane (Bulloch, 1947). Modern anesthesia combines powerful drugs with precise monitoring, making everything from heart transplants to cesarean deliveries possible (Miller, 2010). It's hard to imagine modern medicine without this ability to control pain and consciousness.

Next, when Wilhelm Conrad Röntgen discovered X-rays in 1895, he unlocked a new way to look inside the human body without surgery (Röntgen, 1896). This discovery launched the entire field of medical imaging. Today, CT scans, MRIs, and ultrasounds allow doctors to detect tumors, broken bones, and internal injuries with incredible accuracy (Bushberg & Boone, 2011). Imaging isn't just diagnostic—it's predictive, allowing early detection of disease before symptoms appear. From cancer screening to prenatal care, imaging has become one of the most indispensable tools in medicine.

Furthermore, before the 19th century, doctors believed diseases were caused by "miasmas" or bad air. Louis Pasteur and Robert Koch changed everything when they proved that microorganisms were responsible for infection (Pasteur, 1861; Koch, 1876). Germ theory led to cleaner hospitals, safer surgeries, and ultimately, antiseptics and antibiotics. This shift in understanding did more than save lives—it created the foundation for all modern medicine. As historian Bruno Latour noted, it changed how we think about responsibility and hygiene in everyday life (Latour, 1988). Germ theory is the cornerstone upon which nearly all other breakthroughs rest.

Next, replacing a failing organ with a healthy one was once considered science fiction. That changed in 1954 when Joseph Murray performed the first successful kidney transplant between identical twins (Murray et al., 1955). Advances in immunosuppressive drugs like cyclosporine made organ transplants more widely possible (Calne et al., 1978). Liver, heart, and even lung transplants are now routine in many countries. Organ transplantation doesn't just save lives—it also represents an incredible collaboration between surgery, immunology, and ethics (Starzl, 1963). The continuing shortage of donor organs keeps driving research into artificial and lab-grown alternatives.

Moreover, the discovery of DNA's double helix by Watson and Crick in 1953 paved the way for genetic engineering (Watson & Crick, 1953). The ability to manipulate genes reached a new level with the invention of CRISPR-Cas9 in 2012, allowing precise editing of DNA sequences (Doudna & Charpentier, 2014). Genetic engineering has enormous potential for curing inherited diseases, developing new drugs, and improving crops. But it also raises ethical questions about human enhancement and genetic inequality. Still, it's one of the most promising frontiers in modern medicine.

Moving on, for centuries, the heart was seen as too sacred—and too dangerous—to operate on. That changed in the 20th century with advances like the heart-lung machine and coronary bypass surgery. In 1967, Christiaan Barnard performed the first human heart transplant, proving that cardiac surgery could replace a failing heart entirely (Barnard, 1967). Techniques like angioplasty, valve repair, and minimally invasive procedures now save millions of lives every year (Braunwald, 2015). Heart surgery represents the best of modern medicine: skill, courage, and constant innovation.

Next, Joseph Lister revolutionized surgery in the 1860s by introducing carbolic acid to sterilize instruments and wounds (Lister, 1867). Mortality rates from surgery plummeted almost overnight. Antiseptic practices, combined with sterile operating environments, made hospitals far safer and childbirth much less risky (Hauser, 2013). This idea—clean hands, clean tools, clean spaces—seems obvious today, but it marked a turning point in medicine. Without antiseptics, even minor surgeries could still be fatal.

Finally, before the discovery of insulin, diabetes was like a death sentence. In 1921, Frederick Banting and Charles Best isolated insulin from the pancreas and proved it could control blood sugar in diabetic patients (Banting & Best, 1922). Their discovery transformed diabetes from a terminal disease into a manageable condition. Today, biosynthetic insulin and advanced delivery systems like insulin pumps continue to improve patients' quality of life (Bliss, 1982). Insulin is a perfect example of how basic research can turn into a lifesaving treatment used worldwide.

While those ten breakthroughs changed the past, new technologies are shaping the future. Epidemiology, the study of disease patterns, helps control outbreaks and pandemics. John Snow's work tracing cholera in 1854 laid the foundation for modern public health (Snow, 1855). 3D printing now allows doctors to create custom prosthetics and even bio-printed organs (Murphy & Atala, 2014). Meanwhile, artificial intelligence (AI) is transforming diagnostics, from detecting cancer in scans to predicting heart disease risk (Topol, 2019). These innovations suggest that the next revolution in medicine might come not from a single discovery, but from how technologies work together.

Finally, there are many potential applications of genomic medicine. 1. Examination of variation among healthy individuals 2. Understanding disease risk, susceptibility, and etiology 3. Disease prevention 4. Early diagnosis at the preclinical stage (to help modify disease course, e.g., diet and exercise in diabetes) 5. Identification of new disease-related mutations 6. Accurate diagnosis of challenging cases with inconclusive results for clinical parameters 7. Accurate disease classification based on molecular signature 8. Health management (prognosis and predictive markers) 9. Identification of personal drug-related profile 10. Selection of patients for clinical trials 11. Monitoring disease status (e.g., recurrence) 12. Monitoring tumor evolution in response to treatment 13. Developing new targeted therapies, especially for metastatic tumors refractory to treatment

Strategies to increase the cost-effectiveness of genomic screening strategies. 1. Target screening to a high-risk population 2. Focus on chronic diseases 3. Focus screening on diseases with known interventions 4. Identify molecular changes directly related to short-term benefits 5. Limit screening to diseases with a higher prevalence 6. Interpret data in a clinical context (e.g., environmental factors)

National Human Genome Research Institute

Talking Glossary of Genomic and Genetic Terms

The glossary features nearly 250 terms explained in an easy-to-understand way by leading scientists and professionals at the National Human Genome Research Institute.

Each term includes a spoken definition and narrative, and most include an illustration to provide a visual explanation. For the full audio and visual experience, please visit genome.gov/tg

-A-

Adenine
Adenine (A) is one of the four nucleotide bases in DNA, with the other three being cytosine (C), guanine (G) and thymine (T). Within a double-stranded DNA molecule, adenine bases on one strand pair with thymine bases on the opposite strand. The sequence of the four nucleotide bases encodes DNA's information.

Allele
An allele is one of two or more versions of DNA sequence (a single base or a segment of bases) at a given genomic location. An individual inherits two alleles, one from each parent, for any given genomic location where such variation exists. If the two alleles are the same, the individual is homozygous for that allele. If the alleles are different, the individual is heterozygous.

Alternative Splicing
Alternative splicing is a cellular process in which exons from the same gene are joined in different combinations, leading to different, but related, mRNA transcripts. These mRNAs can be translated to produce different proteins with distinct structures and functions — all from a single gene.

Amino Acid
An amino acid is the fundamental molecule that serves as the building block for proteins. There are 20 different amino acids. A protein consists of one or more chains of amino acids (called polypeptides) whose sequence is encoded in a gene. Some amino acids can be synthesized in the body, but others (essential amino acids) cannot and must be obtained from a person's diet.

Aneuploidy
Aneuploidy is an abnormality in the number of chromosomes in a cell due to loss or duplication. In humans, aneuploidy would be any number of chromosomes other than the usual 46.

Animal Model
An animal model is a non-human species used in biomedical research because it can mimic aspects of a biological process or disease found in humans. Animal models (e.g., mice, rats, zebrafish and others) are sufficiently like humans in their anatomy, physiology or response to a pathogen that researchers can extrapolate the results of animal model studies to better understand human physiology and disease. By using animal models, researchers can perform experiments that would be impractical or ethically prohibited with humans.

Anticodon
A codon is a DNA or RNA sequence of three nucleotides (a trinucleotide) that forms a unit of genetic information encoding a particular amino acid. An anticodon is a trinucleotide sequence located at one end of a transfer RNA (tRNA) molecule, which is complementary to a corresponding codon in a messenger RNA (mRNA) sequence. Each time an amino acid is added to a growing polypeptide during protein synthesis, a tRNA anticodon pairs with its complementary codon on the mRNA molecule, ensuring that the appropriate amino acid is inserted into the polypeptide.

Antisense
Antisense is the non-coding DNA strand of a gene. In a cell, antisense DNA serves as the template for producing messenger RNA (mRNA), which directs the synthesis of a protein.

Autism
Autism is a condition related to brain development that can cause significant social, communication and behavioral challenges. Symptoms usually appear before the age of three. The exact cause of autism is not entirely known, although genetics clearly plays an important role. Autism is one of a group of related developmental conditions sometimes called the autism spectrum that affect people differently and to varying degrees.

Autosomal Dominant Disorder
Autosomal dominant is a pattern of inheritance characteristic of some genetic disorders. “Autosomal” means that the gene in question is located on one of the numbered, or non-sex, chromosomes. “Dominant” means that a single copy of the mutated gene (from one parent) is enough to cause the disorder. A child of a person affected by an autosomal dominant condition has a 50% chance of being affected by that condition via inheritance of a dominant allele. By contrast, an autosomal recessive disorder requires two copies of the mutated gene (one from each parent) to cause the disorder. Huntington’s disease is an example of an autosomal dominant genetic disorder.

Autosomal Recessive Disorder
Autosomal recessive is a pattern of inheritance characteristic of some genetic disorders. “Autosomal” means that the gene in question is located on one of the numbered, or non-sex, chromosomes. “Recessive” means that two copies of the mutated gene (one from each parent) are required to cause the disorder. In a family where both parents are carriers and do not have the disease, roughly a quarter of their children will inherit two disease-causing alleles and have the disease. By contrast, an autosomal dominant disorder requires only a single copy of the mutated gene from one parent to cause the disorder. Sickle cell anemia is an example of an autosomal recessive genetic disorder.

Autosome
An autosome is one of the numbered chromosomes, as opposed to the sex chromosomes. Humans have 22 pairs of autosomes and one pair of sex chromosomes (XX or XY). Autosomes are numbered roughly in relation to their sizes. The largest autosome — chromosome 1 — has approximately 2,800 genes; the smallest autosome — chromosome 22 — has approximately 750 genes.

-B-

Base Pair
A base pair consists of two complementary DNA nucleotide bases that pair together to form a “rung of the DNA ladder.” DNA is made of two linked strands that wind around each other to resemble a twisted ladder — a shape known as a double helix. Each strand has a backbone made of alternating sugar (deoxyribose) and phosphate groups. Attached to each sugar is one of four bases: adenine (A), cytosine (C), guanine (G) or thymine (T). The two strands are held together by hydrogen bonds between pairs of bases: adenine pairs with thymine, and cytosine pairs with guanine.

Bioinformatics
Bioinformatics, as related to genetics and genomics, is a scientific subdiscipline that involves using computer technology to collect, store, analyze and disseminate biological data and information, such as DNA and amino acid sequences or annotations about those sequences. Scientists and clinicians use databases that organize and index such biological information to increase our understanding of health and disease and, in certain cases, as part of medical care.

Birth Defect
A birth defect (also called a congenital defect) is a physical or physiological abnormality present in a baby at birth. Birth defects can be caused by genetic factors, prenatal events during pregnancy or a combination of both. Some birth defects are easy to see (such as an extra or missing finger), while others (such as an enzyme deficiency) are identified through special tests.

BRCA1/BRCA2

BRCA1 and *BRCA2* are the first two genes found to be associated with inherited forms of breast cancer and ovarian cancer. People with mutations in either *BRCA1* or *BRCA2* have a much higher risk for developing breast, ovarian or other types of cancer than those without mutations in the genes. Both BRCA1 and BRCA2 normally act as tumor suppressors, meaning they help to regulate cell division. Most people have two active copies of these genes. When one of the two copies becomes inactive due to an inherited mutation, a person's cells are left with only one copy. If this remaining copy also becomes inactivated, then uncontrolled cell growth results, which leads to breast, ovarian or other types of cancer.

-C-

Cancer

Cancer is a disease in which some of the body's cells grow uncontrollably. There are many different types of cancer, and each begins when a single cell acquires a genomic change (or mutation) that allows the cell to divide and multiply unchecked. Additional mutations can cause the cancer to spread to other sites. Such mutations can be caused by errors during DNA replication or result from DNA damage due to environmental exposures (such as tobacco smoke or the sun's ultraviolet rays). In certain cases, mutations in cancer genes are inherited, which increases a person's risk of developing cancer.

Cancer-Susceptibility Gene

A cancer-susceptibility gene is a gene that, when changed (or mutated), gives an individual an increased risk for developing cancer. Individuals who have inherited mutations in certain cancer-susceptibility genes have a lifetime risk of cancer that is significantly higher than the general population (e.g., *BRCA1/BRCA2*). Individuals in the high-risk category may benefit from more frequent cancer screens. There are also many gene variants associated with a small increase in risk. In some cases, environmental factors may also play a role.

Candidate Gene

The term candidate gene refers to a gene that is believed to be related to a particular trait, such as a disease or a physical attribute. Because of its genomic location or its known function, the gene is suspected to play a role in that trait, thus making it a candidate for additional study.

Carcinogen

A carcinogen is a substance, organism or agent capable of causing cancer. Carcinogens may occur naturally in the environment (such as ultraviolet rays in sunlight and certain viruses) or may be generated by humans (such as automobile exhaust fumes and cigarette smoke). Most carcinogens work by interacting with a cell's DNA to produce mutations.

Carrier

A carrier, as related to genetics, is an individual who "carries" and can pass on to its offspring a genomic variant (allele) associated with a disease (or trait) that is inherited in an autosomal recessive or sex-linked manner, and who does not show symptoms of that disease (or features of that trait). The carrier has inherited the variant allele from one parent and a normal allele from the other parent. Any offspring of carriers is at risk of inheriting a variant allele from their parents, which would result in that child having the disease (or trait).

Carrier Screening

Carrier screening involves testing to see if a person "carries" a genetic variation (allele) associated with a specific disease or trait. A carrier has inherited a normal and a variant allele for a disease- or trait-associated gene, one from each parent. Most typically, carrier screening is performed to look for recessively inherited diseases when the suspected carrier has no symptoms of the disease, but that person's offspring could have the disease if the other parent is a carrier of a harmful variant in the same gene.

Cell-Free DNA Testing

Cell-free DNA testing is a laboratory method that involves analyzing free (i.e., non-cellular) DNA contained within a biological sample, most often to look for genomic variants associated with a hereditary or genetic disorder. For example, prenatal cell-free DNA testing is a non-invasive method used during pregnancy that examines the fetal DNA that is naturally present in the maternal bloodstream. Cell-free DNA testing is also used for the detection and characterization of some cancers and to monitor cancer therapy.

Centimorgan (cM)

A centimorgan (abbreviated cM) is a unit of measure for the frequency of genetic recombination. One centimorgan is equal to a 1% chance that two markers on a chromosome will become separated from one another due to a recombination event during meiosis (which occurs during the formation of egg and sperm cells). On average, one centimorgan corresponds to roughly 1 million base pairs in the human genome.

Central Dogma

The central dogma of molecular biology is a theory stating that genetic information flows only in one direction, from DNA to RNA to protein (or RNA to protein).

Centromere

The centromere appears as a constricted region of a chromosome and plays a key role in helping the cell divide up its DNA during division (mitosis and meiosis). Specifically, it is the region where the cell's spindle fibers attach. Following attachment of the spindle fibers to the centromere, the two identical sister chromatids that make up the replicated chromosome are pulled to opposite sides of the dividing cell, such that the two resulting daughter cells end up with identical DNA.

Chromatid

A chromatid is one of the two identical halves of a chromosome that has been replicated in preparation for cell division. The two “sister” chromatids are joined at a constricted region of the chromosome called the centromere. During cell division, spindle fibers attach to the centromere and pull each of the sister chromatids to opposite sides of the cell. Soon after, the cell divides in two, resulting in daughter cells with identical DNA.

Chromatin

Chromatin refers to a mixture of DNA and proteins that form the chromosomes found in the cells of humans and other higher organisms. Many of the proteins — namely, histones — package the massive amount of DNA in a genome into a highly compact form that can fit in the cell nucleus.

Chromosome

Chromosomes are threadlike structures made of protein and a single molecule of DNA that serve to carry the genomic information from cell to cell. In plants and animals (including humans), chromosomes reside in the nucleus of cells. Humans have 22 pairs of numbered chromosomes (autosomes) and one pair of sex chromosomes (XX or XY), for a total of 46. Each pair contains two chromosomes, one coming from each parent, which means that children inherit half of their chromosomes from their mother and half from their father. Chromosomes can be seen through a microscope when the nucleus dissolves during cell division.

Cloning

Cloning, as it relates to genetics and genomics, involves using scientific methods to make identical, or virtually identical, copies of an organism, cell or DNA sequence. The phrase “molecular cloning” typically refers to isolating and copying a particular DNA segment of interest for further study.

Codominance

Codominance, as it relates to genetics, refers to a type of inheritance in which two versions (alleles) of the same gene are expressed separately to yield different traits in an individual. That is, instead of one trait being dominant over the other, both traits appear, such as in a plant or animal that has more than one pigment color.

Codon

A codon is a DNA or RNA sequence of three nucleotides (a trinucleotide) that forms a unit of genomic information encoding a particular amino acid or signaling the termination of protein synthesis (stop signals). There are 64 different codons: 61 specify amino acids and 3 are used as stop signals.

Complex Disease

A complex disease (or condition), when discussed in the context of genetics, reflects a disorder that results from the contributions of multiple genomic variants and genes in conjunction with significant influences of the physical and social environment. For this reason, complex diseases are also called multifactorial diseases. This stands in contrast to a “simple” genetic disease that is more directly caused by mutations in a single gene. Common examples of complex genetic diseases include heart disease, diabetes and cancer.

Congenital

Congenital refers to a condition or trait that exists at birth. Congenital conditions or traits may be hereditary or result from an action or exposure occurring during pregnancy or at birth, or they may be due to a combination of these factors.

Contig

A contig (as related to genomic studies; derived from the word “contiguous”) is a set of DNA segments or sequences that overlap in a way that provides a contiguous representation of a genomic region. For example, a clone contig provides a physical map of a set of cloned segments of DNA across a genomic region, while a sequence contig provides the actual DNA sequence of a genomic region.

Copy DNA (cDNA)

cDNA (short for copy DNA; also called complementary DNA) is synthetic DNA that has been transcribed from a specific mRNA through a reaction using the enzyme reverse transcriptase. While DNA is composed of both coding and non-coding sequences, cDNA contains only coding sequences. Scientists often synthesize and use cDNA as a tool in gene cloning and other research experiments.

Copy Number Variation (CNV)

Copy number variation (abbreviated CNV) refers to a circumstance in which the number of copies of a specific segment of DNA varies among different individuals’ genomes. The individual variants may be short or include thousands of bases. These structural differences may have come about through duplications, deletions or other changes and can affect long stretches of DNA. Such regions may or may not contain a gene(s).

CRISPR

CRISPR (short for “clustered regularly interspaced short palindromic repeats”) is a technology that research scientists use to selectively modify the DNA of living organisms. CRISPR was adapted for use in the laboratory from naturally occurring genome editing systems found in bacteria.

Crossing Over

Crossing over, as related to genetics and genomics, refers to the exchange of DNA between paired homologous chromosomes (one from each parent) that occurs during the development of egg and sperm cells (meiosis). This process results in new combinations of alleles in the gametes (egg or sperm) formed, which ensures genomic variation in any offspring produced.

Cystic Fibrosis (CF)

Cystic fibrosis (abbreviated CF) is a genetic disorder that causes mucus to build up in certain organs of the body, particularly the lungs and pancreas, resulting in breathing problems, respiratory infections and faulty digestion. Caused by a mutation in a single gene (called *CFTR*), the disorder is inherited as an autosomal recessive trait, meaning that an affected individual inherits two mutated copies of the gene, one from each parent. In the past, CF was almost always fatal in childhood. Today, however, with improvements in screening and treatments, individuals with CF may live into their 30s or 40s, or even longer.

Cytogenetics

Cytogenetics is a branch of biology focused on the study of chromosomes and their inheritance, especially as applied to medical genetics. Chromosomes are microscopic structures containing DNA that reside within the nucleus of a cell. During cell division, these structures become condensed and are visible with a microscope. Special staining techniques can be used to assess the number and structure of a person’s chromosomes as part of diagnostic testing. The number and/or structure of chromosomes is known to be altered in certain genetic diseases.

Cytosine

Cytosine (C) is one of the four nucleotide bases in DNA, with the other three being adenine (A), guanine (G) and thymine (T). Within a double-stranded DNA molecule, cytosine bases on one strand pair with guanine bases on the opposite strand. The sequence of the four nucleotide bases encodes DNA’s information.

-D-

Data Science
Data science involves the study of large, complex data sets that arise from various types of research projects. With respect to genomic studies, such work requires expertise in quantitative scientific disciplines such as bioinformatics, computational biology and biostatistics.

Deletion
A deletion, as related to genomics, is a type of mutation that involves the loss of one or more nucleotides from a segment of DNA. A deletion can involve the loss of any number of nucleotides, from a single nucleotide to an entire piece of a chromosome.

Deoxyribonucleic Acid (DNA)
Deoxyribonucleic acid (abbreviated DNA) is the molecule that carries genetic information for the development and functioning of an organism. DNA is made of two linked strands that wind around each other to resemble a twisted ladder — a shape known as a double helix. Each strand has a backbone made of alternating sugar (deoxyribose) and phosphate groups. Attached to each sugar is one of four bases: adenine (A), cytosine (C), guanine (G) or thymine (T). The two strands are connected by chemical bonds between the bases: adenine bonds with thymine, and cytosine bonds with guanine. The sequence of the bases along DNA's backbone encodes biological information, such as the instructions for making a protein or RNA molecule.

Diploid
Diploid is a term that refers to the presence of two complete sets of chromosomes in an organism's cells, with each parent contributing a chromosome to each pair. Humans are diploid, and most of the body's cells contain 23 chromosomes pairs. Human gametes (egg and sperm cells), however, contain a single set of chromosomes and are said to be haploid.

DNA Fingerprinting
DNA fingerprinting is a laboratory technique used to determine the probable identity of a person based on the nucleotide sequences of certain regions of human DNA that are unique to individuals. DNA fingerprinting is used in a variety of situations, such as criminal investigations, other forensic purposes and paternity testing. In these situations, one aims to "match" two DNA fingerprints with one another, such as a DNA sample from a known person and one from an unknown person.

DNA Replication
DNA replication is the process by which the genome's DNA is copied in cells. Before a cell divides, it must first copy (or replicate) its entire genome so that each resulting daughter cell ends up with its own complete genome.

DNA Sequencing
DNA sequencing refers to the general laboratory technique for determining the exact sequence of nucleotides, or bases, in a DNA molecule. The sequence of the bases (often referred to by the first letters of their chemical names: A, T, C, and G) encodes the biological information that cells use to develop and operate. Establishing the sequence of DNA is key to understanding the function of genes and other parts of the genome. There are now several different methods available for DNA sequencing, each with its own characteristics, and the development of additional methods represents an active area of genomics research.

Dominant Traits and Alleles
Dominant, as related to genetics, refers to the relationship between an observed trait and the two inherited versions of a gene related to that trait. Individuals inherit two versions of each gene, known as alleles, from each parent. In the case of a dominant trait, only one copy of the dominant allele is required to express the trait. The effect of the other allele (the recessive allele) is masked by the dominant allele. Typically, an individual who carries two copies of a dominant allele exhibits the same trait as those who carry only one copy. This contrasts to a recessive trait, which requires that both alleles be present to express the trait.

Double Helix

Double helix, as related to genomics, is a term used to describe the physical structure of DNA. A DNA molecule is made up of two linked strands that wind around each other to resemble a twisted ladder in a helix-like shape. Each strand has a backbone made of alternating sugar (deoxyribose) and phosphate groups. Attached to each sugar is one of four bases: adenine (A), cytosine (C), guanine (G) or thymine (T). The two strands are connected by chemical bonds between the bases: adenine bonds with thymine, and cytosine bonds with guanine.

Down Syndrome (Trisomy 21)

Down syndrome (also called Trisomy 21) is a genetic condition caused by an error in the process that replicates and then divides up the pairs of chromosomes during cell division, resulting in the inheritance of an extra full or partial copy of chromosome 21 from a parent. This extra chromosomal DNA causes the intellectual disabilities and physical features characteristic of Down syndrome, which vary among individuals.

Duplication

Duplication, as related to genomics, refers to a type of mutation in which one or more copies of a DNA segment (which can be as small as a few bases or as large as a major chromosomal region) is produced. Duplications occur in all organisms. For example, they are especially prominent in plants, although they can also cause genetic diseases in humans. Duplications have been an important mechanism in the evolution of the genomes of humans and other organisms.

-E-

Electrophoresis

Electrophoresis is a laboratory technique used to separate DNA, RNA or protein molecules based on their size and electrical charge. An electric current is used to move the molecules through a gel or other matrix. Pores in the gel or matrix work like a sieve, allowing smaller molecules to move faster than larger molecules. To determine the size of the molecules in a sample, standards of known sizes are separated on the same gel and then compared to the sample.

Environmental Factors

Environmental factors, as related to genetics, refers to exposures to substances (such as pesticides or industrial waste) where we live or work, behaviors (such as smoking or poor diet) or stressful situations (such as racism) that can increase an individual’s risk of disease. Genetic studies often take environmental factors into consideration, as these exposures can increase an individual’s risk of genetic damage or disease.

Epigenetics

Epigenetics (also sometimes called epigenomics) is a field of study focused on changes in DNA that do not involve alterations to the underlying sequence. The DNA letters and the proteins that interact with DNA can have chemical modifications that change the degrees to which genes are turned on and off. Certain epigenetic modifications may be passed on from parent cell to daughter cell during cell division or from one generation to the next. The collection of all epigenetic changes in a genome is called an epigenome.

Epistasis

Epistasis is a circumstance where the expression of one gene is modified (e.g., masked, inhibited or suppressed) by the expression of one or more other genes.

Eugenics

Eugenics is a discredited belief that selective breeding for certain inherited human traits can improve the “fitness” of future generations. For eugenicists, “fitness” corresponded to a narrow view of humanity and society that developed directly from the ideologies and practices of scientific racism, colonialism, ableism and imperialism.

Evolution

Evolution, as related to genomics, refers to the process by which living organisms change over time through changes in the genome. Such evolutionary changes result from mutations that produce genomic variation, giving rise to individuals whose biological functions or physical traits are altered. Those individuals who are best at adapting to their surroundings leave behind more offspring than less well-adapted individuals. Thus, over successive generations (in some cases spanning millions of years), one species may evolve to take on divergent functions or physical characteristics or may even evolve into a different species.

Exome
An exome is the sequence of all the exons in a genome, reflecting the protein-coding portion of a genome. In humans, the exome is about 1.5% of the genome.

Exon
An exon is a region of the genome that ends up within an mRNA molecule. Some exons are coding, in that they contain information for making a protein, whereas others are non-coding. Genes in the genome consist of exons and introns.

-F-

Family History
A family history, as related to medicine, is a record of the diseases and health conditions of an individual and that person's biological family members, both living and deceased. A family history can help determine whether someone has an increased genetic risk of having or developing certain diseases, disorders or conditions. It is often recorded by drawing a pedigree (a family tree) that illustrates the relationships among individuals.

Fibroblast
A fibroblast is a type of cell that contributes to the formation of connective tissue, a fibrous cellular material that supports and connects other tissues or organs in the body. Fibroblasts secrete collagen proteins that help maintain the structural framework of tissues. They also play an important role in healing wounds. Obtained from a person through a simple skin biopsy, fibroblasts can be grown in the laboratory for use in genetic and other scientific studies of that individual.

First-Degree Relative
A first-degree relative is a family member who shares about half of their genetic information with specific other individuals in their family. First-degree relatives include an individual's parents, siblings and offspring.

Fluorescence In Situ Hybridization (FISH)
Fluorescence in situ hybridization (abbreviated FISH) is a laboratory technique used to detect and locate a specific DNA sequence on a chromosome. In this technique, the full set of chromosomes from an individual is affixed to a glass slide and then exposed to a "probe"—a small piece of purified DNA tagged with a fluorescent dye. The fluorescently labeled probe finds and then binds to its matching sequence within the set of chromosomes. With the use of a special microscope, the chromosome and sub-chromosomal location where the fluorescent probe bound can be seen.

Founder Effect
A founder effect, as related to genetics, refers to the reduction in genomic variability that occurs when a small group of individuals becomes separated from a larger population. Over time, the resulting new subpopulation will have genotypes and physical traits resembling the initial small, separated group, and these may be very different from the original larger population. A founder effect can also explain why certain inherited diseases are found more frequently in some limited population groups. In some cases, a founder effect can play a role in the emergence of new species.

Fragile X Syndrome
Fragile X syndrome is a genetic condition that affects a person's development, in particular their ability to learn and their social behavior. The syndrome results from mutations in a gene on the X chromosome. Because males have only one copy of the X chromosome, they are more likely to show severe symptoms if they inherit the mutated gene compared to females (who have two copies of the X chromosome).

Frameshift Mutation
A frameshift mutation in a gene refers to the insertion or deletion of nucleotide bases in numbers that are not multiples of three. This is important because a cell reads a gene's code in groups of three bases when making a protein. Each of these "triplet codons" corresponds to one of 20 different amino acids used to build a protein. If a mutation disrupts this normal reading frame, then the entire gene sequence following the mutation will be incorrectly read. This can result in the addition of the wrong amino acids to the protein and/or the creation of a codon that stops the protein from growing longer.

Fraternal Twins
Fraternal twins (also called dizygotic twins) result from the fertilization of two separate eggs with two different sperm during the same pregnancy. Fraternal twins may not have the same sex or appearance. They share half their genomes, just like any other siblings. In contrast, identical twins (or monozygotic twins) result from the fertilization of a single egg by a single sperm, with the fertilized egg then splitting into two. As a result, identical twins share the same genomes and are always the same sex.

-G-

Gamete
A gamete is a reproductive cell of an animal or plant. In animals, female gametes are called ova or egg cells, and male gametes are called sperm. Ova and sperm are haploid cells, with each cell carrying only one copy of each chromosome. During fertilization, a sperm and ovum unite to form a new diploid organism.

Gender
Gender is an evolving term, and there are different definitions. In a general sense, gender involves how a person identifies along a broad, fluid spectrum, rather than strictly by the sex assignment they received at birth. Sex refers to the physical differences (e.g., chromosome composition, anatomy, and physiology) among people who are born male, female, or intersex. The term gender may also be used to refer to the social or cultural constructs of “roles” or “norms” typically associated with being masculine or feminine. Gender does not always directly relate to sex assigned at birth.

Gene
The gene is considered the basic unit of inheritance. Genes are passed from parents to offspring and contain the information needed to specify physical and biological traits. Most genes code for specific proteins, or segments of proteins, which have differing functions within the body. Humans have approximately 20,000 protein-coding genes.

Gene Amplification
Gene amplification refers to an increase in the number of copies of a gene in a genome. Cancer cells, for example, sometimes produce multiple copies of a gene(s) in response to signals from other cells or the environment.

Gene–Environment Interaction
Gene–environment interaction refers to the interplay of genes (and, more broadly, genome function) and the physical and social environment. These interactions influence the expression of phenotypes. For example, most human traits and diseases are influenced by how one or more genes interact in complex ways with environmental factors, such as chemicals in the air or water, nutrition, ultraviolet radiation from the sun, and social context.

Gene Expression
Gene expression is the process by which the information encoded in a gene is used to either make RNA molecules that code for proteins or to make non-coding RNA molecules that serve other functions. Gene expression acts as an “on/off switch” to control when and where RNA molecules and proteins are made and as a “volume control” to determine how much of those products are made. The process of gene expression is carefully regulated, changing substantially under different conditions. The RNA and protein products of many genes serve to regulate the expression of other genes.

Gene Mapping
Gene mapping refers to the process of determining the location of genes on chromosomes. Today, the most efficient approach for gene mapping involves sequencing a genome and then using computer programs to analyze the sequence to identify the location of genes.

Gene Pool
A gene pool refers to the combination of all the genes (including alleles) present in a reproducing population or species. A large gene pool has extensive genomic diversity and is better able to withstand environmental challenges. Inbreeding contributes to a smaller gene pool, making populations or species less able to adapt and survive when faced with environmental challenges.

Gene Regulation
Gene regulation is the process used to control the timing, location and amount in which genes are expressed. The process can be complicated and is carried out by a variety of mechanisms, including through regulatory proteins and chemical modification of DNA. Gene regulation is key to the ability of an organism to respond to environmental changes.

Gene Therapy

Gene therapy is a technique that uses a gene(s) to treat, prevent or cure a disease or medical disorder. Often, gene therapy works by adding new copies of a gene that is broken, or by replacing a defective or missing gene in a patient's cells with a healthy version of that gene. Both inherited genetic diseases (e.g., hemophilia and sickle cell disease) and acquired disorders (e.g., leukemia) have been treated with gene therapy.

Genetic Ancestry

Genetic ancestry refers to information about the people that an individual is biologically descended from, including their genetic relationships. Genetic information can be combined with historical information to infer where an individual's distant ancestors lived.

Genetic Code

Genetic code refers to the instructions contained in a gene that tell a cell how to make a specific protein. Each gene's code uses the four nucleotide bases of DNA — adenine (A), cytosine (C), guanine (G) and thymine (T) — in various ways to spell out three-letter "codons" that specify which amino acid is needed at each position within a protein.

Genetic Counseling

Genetic counseling refers to guidance relating to genetic disorders that a specialized healthcare professional (genetic counselor) provides to an individual or family. A genetic counselor might provide information about how a genetic condition could affect an individual or family and/or interpret genetic tests designed to help estimate the risk of a disease. The genetic counselor conveys information to address the concerns of the individual or family, helps them make an informed decision about their medical situation and provides psychological counseling to help them adapt to their condition or risk.

Genetic Discrimination

Genetic discrimination refers to the unequal treatment of individuals based on an aspect of their genetic code (or genome), such as the risk for a genetic disorder. Genetic discrimination can involve such genomic information being used against individuals in a variety of circumstances, such as employment, health or disability insurance, or education. In a healthcare context, it can refer to people being treated in a discriminatory way based on their genetic status rather than by more relevant criteria.

Genetic Drift

Genetic drift is a mechanism of evolution characterized by random fluctuations in the frequency of a particular version of a gene (allele) in a population. Though it primarily affects small, isolated populations, the effects of genetic drift can be strong, sometimes causing traits to become overwhelmingly frequent or to disappear from a population.

Genetic Engineering

Genetic engineering (also called genetic modification) is a process that uses laboratory-based technologies to alter the DNA makeup of an organism. This may involve changing a single base pair (A-T or C-G), deleting a region of DNA or adding a new segment of DNA. For example, genetic engineering may involve adding a gene from one species to an organism from a different species to produce a desired trait. Used in research and industry, genetic engineering has been applied to the production of cancer therapies, brewing yeasts, genetically modified plants and livestock, and more.

Genetic Epidemiology

Genetic epidemiology is a field of science focused on the study of how genetic factors influence human traits, such as human health and disease. In many cases, the interaction of genes with the environment is also measured. Genetic epidemiologists seek to understand the causes, distribution and control of inherited disease in groups and the multifactorial causes of genetic diseases in populations.

Genetic Imprinting

Genetic imprinting (also called genomic imprinting) is the process by which only one copy of a gene in an individual (either from their mother or their father) is expressed, while the other copy is suppressed. Unlike genomic mutations that can affect the ability of inherited genes to be expressed, genetic imprinting does not affect the DNA sequence itself. Instead, gene expression is silenced by the epigenetic addition of chemical tags to the DNA during egg or sperm formation. Epigenetic tags on imprinted genes usually stay in place for the life of the individual.

Genetic Information Nondiscrimination Act (GINA)

The Genetic Information Nondiscrimination Act (abbreviated GINA) is federal legislation in the United States that protects individuals against discrimination based on their personal genetic information, as it applies to health insurance and employment. These protections are intended to encourage Americans to take advantage of genetic testing as part of their medical care. GINA was signed into law on May 22, 2008.

Genetic Map

A genetic map (also called a linkage map) shows the relative location of genetic markers (reflecting sites of genomic variants) on a chromosome. A genetic map is based on the concept of genetic linkage: the closer two markers are to each other on a chromosome, the greater the probability that they will be inherited together. By studying inheritance patterns, the relative order and location of genetic markers along a chromosome can be established.

Genetic Testing

Genetic testing is the use of a laboratory test to examine an individual's DNA for variations, typically performed in the context of medical care, ancestry studies or forensics. In a medical setting, the results of a genetic test can be used to confirm or rule out a suspected genetic disease. Results may also be used to determine the likelihood of parents passing on a genetic mutation to their offspring. Genetic testing may be performed prenatally or after birth. Genetic testing is also used to study the genomes of tumors in cancer cases.

Genetics

Genetics is the branch of biology concerned with the study of inheritance, including the interplay of genes, DNA variation and their interactions with environmental factors.

Genome

The genome is the entire set of DNA instructions found in a cell. In humans, the genome consists of 23 pairs of chromosomes located in the cell's nucleus, as well as a small chromosome in the cell's mitochondria. A genome contains all the information needed for an individual to develop and function.

Genome-Wide Association Study (GWAS)

A genome-wide association study (abbreviated GWAS) is a research approach used to identify genomic variants that are statistically associated with a risk for a disease or a particular trait. The method involves surveying the genomes of many people, looking for genomic variants that occur more frequently in those with a specific disease or trait compared to those without the disease or trait. Once such genomic variants are identified, they are typically used to search for nearby variants that contribute directly to the disease or trait.

Genomic Medicine

Genomic medicine is a medical discipline that involves using a person's genomic information as part of their clinical care. Other similar terms include individualized medicine, personalized medicine and precision medicine. For some conditions, genomic information can be used to help diagnose disease, predict outcomes and guide treatment.

Genomic Variation

Genomic variation refers to DNA sequence differences among individuals or populations. Some variants influence biological function (such as a mutation that causes a genetic disease), while others have no biological effects.

Genomics

Genomics is a field of biology focused on studying all the DNA of an organism — that is, its genome. Such work includes identifying and characterizing all the genes and functional elements in an organism's genome as well as how they interact.

Genotype

A genotype is a scoring of the type of variant present at a given location (i.e., a locus) in the genome. It can be represented by symbols. For example, BB, Bb, bb could be used to represent a given variant in a gene. Genotypes can also be represented by the actual DNA sequence at a specific location, such as CC, CT, TT. DNA sequencing and other methods can be used to determine the genotypes at millions of locations in a genome in a single experiment. Some genotypes contribute to an individual's observable traits, called the phenotype.

Germ Line

Germ line refers to the sex cells (eggs and sperm) that sexually reproducing organisms use to pass on their genomes from one generation to the next (parents to offspring). Egg and sperm cells are called germ cells, in contrast to the other cells of the body, which are called somatic cells.

Gigabase (Gb)

A gigabase (abbreviated Gb) is a unit of measurement used to help designate the length of DNA. One gigabase is equal to 1 billion bases.

GMO (Genetically Modified Organism)

GMO (short for “genetically modified organism”) is a plant, animal or microbe in which one or more changes have been made to the genome, typically using high-tech genetic engineering, in an attempt to alter the characteristics of an organism. Genes can be introduced, enhanced or deleted within a species, across species or even across kingdoms. GMOs may be used for a variety of purposes, such as making human insulin, producing fermented beverages and developing pesticide resistance in crop plants.

Guanine

Guanine (G) is one of the four nucleotide bases in DNA, with the other three being adenine (A), cytosine (C) and thymine (T). Within a double-stranded DNA molecule, guanine bases on one strand pair with cytosine bases on the opposite strand. The sequence of the four nucleotide bases encodes DNA’s information.

-H-

Haploid

Haploid refers to the presence of a single set of chromosomes in an organism’s cells. Sexually reproducing organisms are diploid (having two sets of chromosomes, one from each parent). In humans, only the egg and sperm cells are haploid.

Haplotype

A haplotype is a physical grouping of genomic variants (or polymorphisms) that tend to be inherited together. A specific haplotype typically reflects a unique combination of variants that reside near each other on a chromosome.

Heterozygous

Heterozygous, as related to genetics, refers to having inherited different versions (alleles) of a genomic marker from each biological parent. Thus, an individual who is heterozygous for a genomic marker has two different versions of that marker. By contrast, an individual who is homozygous for a marker has identical versions of that marker.

Histone

A histone is a protein that provides structural support for a chromosome. Each chromosome contains a long molecule of DNA, which must fit into the cell nucleus. To do that, the DNA wraps around complexes of histone proteins, giving the chromosome a more compact shape. Histones also play a role in the regulation of gene expression.

Homologous Recombination

Homologous recombination is a type of genetic recombination in which nucleotide sequences are exchanged between two similar or identical molecules of DNA. During the formation of egg and sperm cells (meiosis), paired chromosomes from the male and female parents align so that similar DNA sequences can cross over, or be exchanged, from one chromosome to the other. This exchanging of DNA is an important source of the genomic variation seen among offspring.

Homozygous

Homozygous, as related to genetics, refers to having inherited the same versions (alleles) of a genomic marker from each biological parent. Thus, an individual who is homozygous for a genomic marker has two identical versions of that marker. By contrast, an individual who is heterozygous for a marker has two different versions of that marker.

Human Genome Project

The Human Genome Project was a large international, collaborative effort that mapped and sequenced the human genome for the first time. Conducted from 1990 to 2003, the project was historic in its scope and scale as well as its groundbreaking approach for the free release of genomic data well ahead of publication, leading to a new ethos for data sharing in biomedical research.

Human Genome Reference Sequence

A human genome reference sequence is an accepted representation of the human genome sequence that is used by researchers as a standard for comparison to DNA sequences generated in their studies. The scientists responsible for assembling and updating such reference sequences aim to provide the highest-quality, best possible consensus representations of the sequence and structural diversity found in the human genome among populations. The genome reference sequence provides a general framework and is not the DNA sequence of a single person.

Huntington’s Disease

Huntington’s disease is a rare inherited disorder associated with the progressive loss of brain and muscle function. Symptoms usually develop during middle age and may include uncontrolled movements, loss of intellectual abilities and various emotional and psychiatric symptoms. Huntington’s disease is inherited as an autosomal dominant trait, meaning that a single mutated copy of the responsible gene (called *HTT*) is sufficient to cause the disease.

Hybridization

Hybridization, as related to genomics, is the process in which two complementary single-stranded DNA and/or RNA molecules bond together to form a double-stranded molecule. The bonding is dependent on the appropriate base-pairing across the two single-stranded molecules. Hybridization is an important process in various research and clinical laboratory techniques.

-I-

Identical Twins

Identical twins (also called monozygotic twins) result from the fertilization of a single egg by a single sperm, with the fertilized egg then splitting into two. Identical twins share the same genomes and are always of the same sex. In contrast, fraternal (dizygotic) twins result from the fertilization of two separate eggs with two different sperm during the same pregnancy. They share half of their genomes, just like any other siblings. Fraternal twins may not be of the same sex or have similar appearances.

In Situ Hybridization

In situ hybridization is a laboratory technique used to localize a sequence of DNA or RNA in a biological sample. In this technique, a biological sample consisting of tissue sections, cells or chromosomes from an individual is affixed to a glass slide and then exposed to a “probe”—a small piece of single-stranded DNA tagged with a chemical or fluorescent dye. The labeled probe finds and then binds to its matching sequence within the biological sample. The location of the bound probe can then be seen with the use of a microscope.

Inherited

Inherited, as related to genetics, refers to a trait or variants encoded in DNA and passed from parent to offspring during reproduction. Inheritance is determined by the rules of Mendelian genetics.

Insertion

An insertion, as related to genomics, is a type of mutation that involves the addition of one or more nucleotides into a segment of DNA. An insertion can involve the addition of any number of nucleotides, from a single nucleotide to an entire piece of a chromosome.

Intergenic Regions

Intergenic regions are the stretches of DNA located between genes. In humans, intergenic regions are non-protein-coding and comprise a large majority of the genome. Some intergenic DNA is known to regulate the expression of nearby genes.

Intron

An intron is a region that resides within a gene but does not remain in the final mature mRNA molecule following transcription of that gene and does not code for amino acids that make up the protein encoded by that gene. Most protein-coding genes in the human genome consist of exons and introns.

Inversion

An inversion in a chromosome occurs when a segment breaks off and reattaches within the same chromosome, but in reverse orientation. DNA may or may not be lost in the process.

-K-

Karyotype

A karyotype is an individual's complete set of chromosomes. The term also refers to a laboratory-produced image of a person's chromosomes isolated from an individual cell and arranged in numerical order. A karyotype may be used to look for abnormalities in chromosome number or structure.

Kilobase (kb)

A kilobase (abbreviated kb) is a unit of measurement used to help designate the length of DNA or RNA. One kilobase is equal to 1,000 bases.

Knockout

A knockout, as related to genomics, refers to the use of genetic engineering to inactivate or remove one or more specific genes from an organism. Scientists create knockout organisms to study the impact of removing a gene from an organism, which often allows them to then learn something about that gene's function.

-L-

Linkage

Linkage, as related to genetics and genomics, refers to the closeness of genes or other DNA sequences to one another on the same chromosome. The closer two genes or sequences are to each other on a chromosome, the greater the probability that they will be inherited together.

Locus

A locus, as related to genomics, is a physical site or location within a genome (such as a gene or another DNA segment of interest), somewhat like a street address. The plural of locus is loci.

LOD Score

An LOD (short for "logarithm of the odds") score is a statistical estimate of the relative probability that two loci (e.g., a disease-associated gene and another sequence of interest, such as a variant or another gene) are located near each other on a chromosome and are therefore likely to be inherited together.

LOH (Loss of Heterozygosity)

LOH (short for "loss of heterozygosity") refers to a type of mutation that results in the loss of one copy of a segment of DNA (typically containing a gene or group of genes). For most parts of the genome, human cells have two copies of any genomic segment — one from each parent — so in the case of LOH, only one copy would still be present.

Lyonization

Lyonization (also called X-inactivation) refers to the normal phenomenon in which one of the two X chromosomes in every cell of a female individual is inactivated during embryonic development. This inactivation prevents females from having twice as many X chromosome gene products as males, who possess only a single copy of the X chromosome. Lyonization is named after Mary F. Lyon, the British geneticist who discovered the phenomenon.

-M-

Mapping
Mapping refers to the process of determining the relative locations of landmarks or markers (such as genes, variants and other DNA sequences of interest) within a chromosome or genome. Historically, there have been two approaches for mapping: physical mapping, which established maps based on physical distances between landmarks, and genetic mapping, which established maps based on the frequency with which two landmarks are inherited together. Today, the most efficient approach for mapping involves sequencing a genome and then using computer programs to analyze the sequence to identify the locations of landmarks.

Marker
A marker (largely synonymous with the word "landmark" and often referred to as a genomic marker or a genetic marker) is a DNA sequence, typically with a known location in a genome. Markers can reflect random sequences, genomic variants or genes. Markers are used as signposts (or landmarks) in the construction of DNA and genome maps. Markers can also be used to track inheritance of traits or disease risk in families.

Megabase (Mb)
A megabase (abbreviated Mb) is a unit of measurement used to help designate the length of DNA. One megabase is equal to 1 million bases.

Meiosis
Meiosis is a type of cell division in sexually reproducing organisms that reduces the number of chromosomes in gametes (the sex cells, or egg and sperm). In humans, body (or somatic) cells are diploid, containing two sets of chromosomes (one from each parent). To maintain this state, the egg and sperm that unite during fertilization must be haploid, with a single set of chromosomes. During meiosis, each diploid cell undergoes two rounds of division to yield four haploid daughter cells — the gametes.

Mendel, Johann (Gregor)
Gregor Mendel was an Austrian monk in the 19th century who worked out the basic laws of inheritance through experiments with pea plants. In his monastery garden, Mendel performed thousands of crosses with pea plants, discovering how characteristics are passed down from one generation to the next — namely, dominant and recessive traits. Mendel's early experiments provided the basis of modern genetics.

Mendelian Inheritance
Mendelian inheritance refers to certain patterns of how traits are passed from parents to offspring. These general patterns were established by the Austrian monk Gregor Mendel, who performed thousands of experiments with pea plants in the 19th century. Mendel's discoveries of how traits (such as color and shape) are passed down from one generation to the next introduced the concept of dominant and recessive modes of inheritance.

Messenger RNA (mRNA)
Messenger RNA (abbreviated mRNA) is a type of single-stranded RNA involved in protein synthesis. mRNA is made from a DNA template during the process of transcription. The role of mRNA is to carry protein information from the DNA in a cell's nucleus to the cell's cytoplasm (watery interior), where the protein-making machinery reads the mRNA sequence and translates each three-base codon into its corresponding amino acid in a growing protein chain.

Metagenomics
Metagenomics is the study of the structure and function of entire nucleotide sequences isolated and analyzed from all the organisms (typically microbes) in a bulk sample. Metagenomics is often used to study a specific community of microorganisms, such as those residing on human skin, in the soil or in a water sample.

Metaphase
Metaphase is a stage during the process of cell division (mitosis or meiosis). Normally, individual chromosomes are spread out in the cell nucleus. During metaphase, the nucleus dissolves and the cell's chromosomes condense and move together, aligning in the center of the dividing cell. At this stage, the chromosomes are distinguishable when viewed through a microscope. Metaphase chromosomes are used in karyotyping, a laboratory technique for identifying chromosomal abnormalities.

Methylation

Methylation is a chemical modification of DNA and other molecules that may be retained as cells divide to make more cells. When found in DNA, methylation can alter gene expression. In this process, chemical tags called methyl groups attach to a particular location within DNA where they turn a gene on or off, thereby regulating the production of proteins that the gene encodes.

Microarray Technology

Microarray technology is a general laboratory approach that involves binding an array of thousands to millions of known nucleic acid fragments to a solid surface, referred to as a “chip.” The chip is then bathed with DNA or RNA isolated from a study sample (such as cells or tissue). Complementary base pairing between the sample and the chip-immobilized fragments produces light through fluorescence that can be detected using a specialized machine. Microarray technology can be used for a variety of purposes in research and clinical studies, such as measuring gene expression and detecting specific DNA sequences (e.g., single nucleotide polymorphisms, or SNPs).

Microbiome

The microbiome is the community of microorganisms (such as fungi, bacteria and viruses) that exists in a particular environment. In humans, the term is often used to describe the microorganisms that live in or on a particular part of the body, such as the skin or gastrointestinal tract. These groups of microorganisms are dynamic and change in response to a host of environmental factors, such as exercise, diet, medication and other exposures.

Microsatellite

Microsatellite, as related to genomics, refers to a short segment of DNA, usually one to six or more base pairs in length, that is repeated multiple times in succession at a particular genomic location. These DNA sequences are typically non-coding. The number of repeated segments within a microsatellite sequence often varies among people, which makes them useful as polymorphic markers for studying inheritance patterns in families or for creating a DNA fingerprint from crime scene samples.

Missense Mutation

A missense mutation is a DNA change that results in different amino acids being encoded at a particular position in the resulting protein. Some missense mutations alter the function of the resulting protein.

Mitochondrial DNA

Mitochondrial DNA is the circular chromosome found inside the cellular organelles called mitochondria. Located in the cytoplasm, mitochondria are the site of the cell’s energy production and other metabolic functions. Offspring inherit mitochondria — and as a result mitochondrial DNA — from their mother.

Mitosis

Mitosis is the process by which a cell replicates its chromosomes and then segregates them, producing two identical nuclei in preparation for cell division. Mitosis is generally followed by equal division of the cell’s content into two daughter cells that have identical genomes.

Monosomy

Monosomy refers to the condition in which only one chromosome from a pair is present in cells rather than the two copies usually found in diploid cells. When cells have one chromosome from a pair plus a portion of the second chromosome, this is referred to as partial monosomy. Monosomy, or partial monosomy, causes certain human diseases such as Turner syndrome and Cri du chat syndrome.

Mosaicism

Mosaicism refers to the presence of cells in a person that have a different genome from the body’s other cells. This difference could be due to a specific genomic variant, for example, or the addition or loss of a chromosome. The condition can stem from a genetic error that occurs after fertilization of an egg, during very early embryo development, or it could occur later in development. Mosaicism can affect any type of cell and does not always cause disease.

Mutagen

A mutagen is a chemical or physical agent capable of inducing changes in DNA called mutations. Examples of mutagens include tobacco products, radioactive substances, x-rays, ultraviolet radiation and a wide variety of chemicals. Exposure to a mutagen can produce DNA mutations that cause or contribute to certain diseases.

Mutation

A mutation is a change in the DNA sequence of an organism. Mutations can result from errors in DNA replication during cell division, exposure to mutagens or a viral infection. Germline mutations (that occur in eggs and sperm) can be passed on to offspring, while somatic mutations (that occur in body cells) are not passed on.

-N-

Nanopore DNA Sequencing

Nanopore DNA sequencing is a laboratory technique for determining the exact sequence of nucleotides, or bases, in a DNA molecule. The sequence of the bases (often referred to by the first letters of their chemical names: A, T, C and G) encodes the biological information that cells use to develop and operate. Nanopore DNA sequencing involves reading the code of single DNA strands as they are threaded through extremely tiny pores (nanopores) embedded within a membrane. As the DNA moves through the pore, it creates signals that can be converted to read each base. This approach offers a low-cost, rapid process for studying long stretches of DNA.

Nanotechnology

Nanotechnology (often shortened to nanotech) is the understanding and use of matter on an atomic and molecular scale for industrial purposes. Manipulating matter at nanoscale — between approximately 1 and 100 nanometers — holds potential for novel applications in many fields, including genomics, engineering, computer science and medicine.

Newborn Genetic Screening

Newborn screening is a set of laboratory tests performed on newborn babies to detect a set of known genetic diseases. Typically, this testing is performed on a blood sample obtained from a heel prick when the baby is two or three days old. In the United States, newborn screening is mandatory for a defined set of genetic diseases, although the exact set differs from state to state. Newborn screening tests focus on conditions for which early diagnosis is important to treating or preventing disease.

Next-Generation DNA Sequencing

DNA sequencing establishes the order of the bases that make up DNA. Next-generation DNA sequencing (abbreviated NGS) refers to the use of technologies for sequencing DNA that became available shortly after the completion of the Human Genome Project (which relied on the first-generation method of Sanger sequencing). Faster and cheaper than their predecessors, NGS technologies can sequence an entire human genome in a single day and for less than $1,000.

Non-Coding DNA

Non-coding DNA corresponds to the portions of an organism's genome that do not code for amino acids, the building blocks of proteins. Some non-coding DNA sequences are known to serve functional roles, such as in the regulation of gene expression, while other areas of non-coding DNA have no known function.

Nonsense Mutation

A nonsense mutation occurs in DNA when a sequence change gives rise to a stop codon rather than a codon specifying an amino acid. The presence of the new stop codon results in the production of a shortened protein that is likely non-functional.

Northern Blot

Northern blot is a laboratory analysis method used to study RNA. Specifically, purified RNA fragments from a biological sample (such as blood or tissue) are separated by using an electric current to move them through a sieve-like gel or matrix, which allows smaller fragments to move faster than larger fragments. The RNA fragments are transferred out of the gel or matrix onto a solid membrane, which is then exposed to a DNA probe labeled with a radioactive, fluorescent or chemical tag. The tag allows any RNA fragments containing complementary sequences with the DNA probe sequence to be visualized within the Northern blot.

Nuclear Membrane

The nuclear membrane is a double layer that encloses the cell's nucleus, where the chromosomes reside. The nuclear membrane serves to separate the chromosomes from the cell's cytoplasm and other contents. An array of small holes or pores in the nuclear membrane permits the selective passage of certain materials, such as nucleic acids and proteins, between the nucleus and cytoplasm.

Nucleic Acids
Nucleic acids are large biomolecules that play essential roles in all cells and viruses. A major function of nucleic acids involves the storage and expression of genomic information. Deoxyribonucleic acid, or DNA, encodes the information cells need to make proteins. A related type of nucleic acid, called ribonucleic acid (RNA), comes in different molecular forms that play multiple cellular roles, including protein synthesis.

Nucleolus
The nucleolus is a spherical structure found in the cell's nucleus whose primary function is to produce and assemble the cell's ribosomes. The nucleolus is also where ribosomal RNA genes are transcribed. Once assembled, ribosomes are transported to the cell cytoplasm, where they serve as the sites for protein synthesis.

Nucleopore
A nucleopore is one of a series of openings found in the cell's nuclear membrane. Nucleopores serve as channels for the selective transport of nucleic acids and proteins into and out of the cell nucleus.

Nucleosome
A nucleosome is the basic repeating subunit of chromatin packaged inside the cell's nucleus. In humans, about six feet of DNA must be packaged into a nucleus with a diameter less than a human hair, and nucleosomes play a key role in that process. A single nucleosome consists of about 150 base pairs of DNA sequence wrapped around a core of histone proteins. In forming a chromosome, the nucleosomes repeatedly fold in on themselves to tighten and condense the packaged DNA.

Nucleotide
A nucleotide is the basic building block of nucleic acids (RNA and DNA). A nucleotide consists of a sugar molecule (either ribose in RNA or deoxyribose in DNA) attached to a phosphate group and a nitrogen-containing base. The bases used in DNA are adenine (A), cytosine (C), guanine (G) and thymine (T). In RNA, the base uracil (U) takes the place of thymine. DNA and RNA molecules are polymers made up of long chains of nucleotides.

Nucleus
A nucleus, as related to genomics, is the membrane-enclosed organelle within a cell that contains the chromosomes. An array of holes, or pores, in the nuclear membrane allows for the selective passage of certain molecules (such as proteins and nucleic acids) into and out of the nucleus.

-O-

Oncogene
An oncogene is a mutated gene that has the potential to cause cancer. Before an oncogene becomes mutated, it is called a proto-oncogene, and it plays a role in regulating normal cell division. Cancer can arise when a proto-oncogene is mutated, changing it into an oncogene and causing the cell to divide and multiply uncontrollably. Some oncogenes work like an accelerator pedal in a car, pushing a cell to divide again and again. Others work like a faulty brake in a car parked on a hill, also causing the cell to divide unchecked.

Open Reading Frame
An open reading frame, as related to genomics, is a portion of a DNA sequence that does not include a stop codon (which functions as a stop signal). A codon is a DNA or RNA sequence of three nucleotides (a trinucleotide) that forms a unit of genomic information encoding a particular amino acid or signaling the termination of protein synthesis (stop codon). There are 64 different codons: 61 specify amino acids and 3 are used as stop codons. A long open reading frame is often part of a gene (that is, a sequence directly coding for a protein).

-P-

Pedigree

A pedigree, as related to genetics, is a chart that diagrams the inheritance of a trait or health condition through generations of a family. The pedigree particularly shows the relationships among family members and, when the information is available, indicates which individuals have a trait(s) of interest.

Peptide

A peptide is a short chain of amino acids (typically 2 to 50) linked by chemical bonds (called peptide bonds). A longer chain of linked amino acids (51 or more) is a polypeptide. The proteins manufactured inside cells are made from one or more polypeptides.

Pharmacogenomics

Pharmacogenomics (also called pharmacogenetics) is a component of genomic medicine that involves using a patient's genomic information to tailor the selection of drugs used in their medical management. In this way, pharmacogenomics aims to provide a more individualized (or precise) approach to the use of available medication in treating patients.

Phenotype

Phenotype refers to an individual's observable traits, such as height, eye color and blood type. A person's phenotype is determined by both their genomic makeup (genotype) and environmental factors.

Physical Map

A physical map, as related to genomics, is a graphical representation of physical locations of landmarks or markers (such as genes, variants and other DNA sequences of interest) within a chromosome or genome. A complete genome sequence is one type of physical map. Physical maps are used to identify genes or other sequences believed to play a role in health conditions or diseases. They are also valuable in providing an organizational framework for generating complete sequences of genomes.

Plasmid

A plasmid is a small circular DNA molecule found in bacteria and some other microscopic organisms. Plasmids are physically separate from chromosomal DNA and replicate independently. They typically have a small number of genes — notably, some associated with antibiotic resistance — and can be passed from one cell to another. Scientists use recombinant DNA methods to splice genes that they want to study into a plasmid. When the plasmid copies itself, it also makes copies of the inserted gene.

Point Mutation

A point mutation occurs in a genome when a single base pair is added, deleted or changed. While most point mutations are benign, they can also have various functional consequences, including changes in gene expression or alterations in encoded proteins.

Polydactyly

Polydactyly is a condition in which a person has more than the normal number of fingers or toes. It can occur in association with other physical anomalies or intellectual impairment, or it may occur as an isolated birth defect. Polydactyly can either be inherited or it can arise sporadically in an individual.

Polygenic Risk Score (PRS)

A polygenic risk score (abbreviated PRS) uses genomic information alone to assess a person's chances of having or developing a particular medical condition. A person's PRS is a statistical calculation based on the presence or absence of multiple genomic variants, without taking environmental or other factors into account.

Polygenic Trait

A polygenic trait is a characteristic, such as height or skin color, that is influenced by two or more genes. Because multiple genes are involved, polygenic traits do not follow the patterns of Mendelian inheritance. Many polygenic traits are also influenced by the environment and are called multifactorial.

Polymerase Chain Reaction (PCR)

Polymerase chain reaction (abbreviated PCR) is a laboratory technique for rapidly producing (amplifying) millions to billions of copies of a specific segment of DNA, which can then be studied in greater detail. PCR involves using short synthetic DNA fragments called primers to select a segment of the genome to be amplified, and then multiple rounds of DNA synthesis to amplify that segment.

Polymorphism

Polymorphism, as related to genomics, refers to the presence of two or more variant forms of a specific DNA sequence that can occur among different individuals or populations. The most common type of polymorphism involves variation at a single nucleotide (also called a single-nucleotide polymorphism, or SNP). Other polymorphisms can be much larger, involving longer stretches of DNA.

Population Genomics

Population genomics is the large-scale application of genomic technologies to study populations of individuals. For example, population genomics research can be used to study human ancestry, migrations and health.

Positional Cloning

Positional cloning is a laboratory approach used to locate the position of a disease-associated gene on a chromosome. Such a strategy can succeed even when nothing is known about the role of the gene's encoded protein in the disease. The technique typically relies on the use of known polymorphic markers whose inheritance can be traced through various members of families affected by the disease.

Precision Medicine

Precision medicine (generally considered analogous to personalized medicine or individualized medicine) is an innovative approach that uses information about an individual's genomic, environmental and lifestyle information to guide decisions related to their medical management. The goal of precision medicine is to provide more a precise approach for the prevention, diagnosis and treatment of disease.

Primer

A primer, as related to genomics, is a short single-stranded DNA fragment used in certain laboratory techniques, such as the polymerase chain reaction (PCR). In the PCR method, a pair of primers hybridizes with the sample DNA and defines the region that will be amplified, resulting in millions and millions of copies in a very short timeframe. Primers are also used in DNA sequencing and other experimental processes.

Proband

A proband is an individual who is affected by a genetic condition or who is concerned they are at risk. Usually, the proband is the first person in a family who brings the concern of a genetic disorder to the attention of healthcare professionals.

Promoter

A promoter, as related to genomics, is a region of DNA upstream of a gene where relevant proteins (such as RNA polymerase and transcription factors) bind to initiate transcription of that gene. The resulting transcription produces an RNA molecule (such as mRNA).

Protein

Proteins are large, complex molecules that play many important roles in the body. They are critical to most of the work done by cells and are required for the structure, function and regulation of the body's tissues and organs. A protein is made up of one or more long, folded chains of amino acids (each called a polypeptide), whose sequences are determined by the DNA sequence of the protein-encoding gene.

Pseudogene

A pseudogene is a segment of DNA that structurally resembles a gene but is not capable of coding for a protein. Pseudogenes are most often derived from genes that have lost their protein-coding ability due to accumulated mutations that have occurred over the course of evolution.

-R-

Race
Race is a social construct used to group people. Race was constructed as a hierarchal human-grouping system, generating racial classifications to identify, distinguish and marginalize some groups across nations, regions and the world. Race divides human populations into groups often based on physical appearance, social factors and cultural backgrounds.

Recessive Traits and Alleles
Recessive, as related to genetics, refers to the relationship between an observed trait and the two inherited versions of a gene related to that trait. Individuals inherit two versions of each gene, known as alleles, from each parent. In the case of a recessive trait, the alleles of the trait-causing gene are the same, and both (recessive) alleles must be present to express the trait. A recessive allele does not produce a trait at all when only one copy is present. This contrasts to a dominant trait, which requires that only one of the two alleles be present to express the trait.

Recombinant DNA Technology
Recombinant DNA technology involves using enzymes and various laboratory techniques to manipulate and isolate DNA segments of interest. This method can be used to combine (or splice) DNA from different species or to create genes with new functions. The resulting copies are often referred to as recombinant DNA. Such work typically involves propagating the recombinant DNA in a bacterial or yeast cell, whose cellular machinery copies the engineered DNA along with its own.

Repressor
A repressor, as related to genomics, is a protein that inhibits the expression of one or more genes. The repressor protein works by binding to the promoter region of the gene(s), which prevents the production of messenger RNA (mRNA). Repressor proteins are essential for the regulation of gene expression in cells.

Restriction Enzyme
A restriction enzyme is a protein isolated from bacteria that cleaves DNA sequences at sequence-specific sites, producing DNA fragments with a known sequence at each end. The use of restriction enzymes is critical to certain laboratory methods, including recombinant DNA technology and genetic engineering.

Restriction Fragment Length Polymorphism (RFLP)
Restriction fragment length polymorphism (abbreviated RFLP) refers to differences (or variations) among people in their DNA sequences at sites recognized by restriction enzymes. Such variation results in different sized (or length) DNA fragments produced by digesting the DNA with a restriction enzyme. RFLPs can be used as genetic markers, which are often used to follow the inheritance of DNA through families.

Retrovirus
A retrovirus is a virus that uses RNA as its genomic material. Upon infection with a retrovirus, a cell converts the retroviral RNA into DNA, which in turn is inserted into the DNA of the host cell. The cell then produces more retroviruses, which infect other cells. Many retroviruses are associated with diseases, including AIDS and some forms of cancer.

Ribonucleic Acid (RNA)
Ribonucleic acid (abbreviated RNA) is a nucleic acid present in all living cells that has structural similarities to DNA. Unlike DNA, however, RNA is most often single-stranded. An RNA molecule has a backbone made of alternating phosphate groups and the sugar ribose, rather than the deoxyribose found in DNA. Attached to each sugar is one of four bases: adenine (A), uracil (U), cytosine (C) or guanine (G). Different types of RNA exist in cells: messenger RNA (mRNA), ribosomal RNA (rRNA) and transfer RNA (tRNA). In addition, some RNAs are involved in regulating gene expression. Certain viruses use RNA as their genomic material.

Ribosome
A ribosome is an intercellular structure made of both RNA and protein, and it is the site of protein synthesis in the cell. The ribosome reads the messenger RNA (mRNA) sequence and translates that genetic code into a specified string of amino acids, which grow into long chains that fold to form proteins.

Risk

Risk, as related to genetics, refers to the probability that an individual will be affected by a particular heritable or genetic disorder. Both a person's genome and environmental exposures can influence risk. An individual's risk may be higher because they inherit a genetic variant (or allele) in one gene or a combination of many variants in different genes that increases susceptibility to or overtly causes a disorder. Other individuals may be at higher risk because they have been exposed to one or more environmental factors that promote the development of a certain disorder.

-S-

Scientific Racism

Scientific racism is a historical pattern of ideologies that generate and perpetuate pseudoscientific racist beliefs that lead to racial bias and discrimination in science and research. Leading scientists across scientific institutions in the 19th and early 20th centuries were proponents of such ideologies. By the mid-20th century, pseudoscientific racist beliefs were widely disproven. However, evidence shows that scientific racism persists in science and research.

Secondary Genomic Finding

A secondary genomic finding refers to a genomic variant, found through the analysis of a person's genome, that is of potential medical value yet is unrelated to the initial reason for examining the person's genome. In certain cases, a secondary genomic finding might offer clinicians the chance to identify a previously unrecognized risk for disease that could change the medical management of that patient and potentially prevent or more effectively treat the disease.

Sex Chromosome

A sex chromosome is a type of chromosome involved in sex determination. Humans and most other mammals have two sex chromosomes, X and Y, that in combination determine the sex of an individual. Females have two X chromosomes in their cells, while males have one X and one Y.

Sex-Linked

Sex-linked, as related to genetics, refers to characteristics (or traits) that are influenced by genes carried on the sex chromosomes. In humans, the term often refers to traits or disorders influenced by genes on the X chromosome, as it contains many more genes than the smaller Y chromosome. Males, who have only a single copy of the X chromosome, are more likely to be affected by a sex-linked disorder than females, who have two copies. In females, the presence of a second, non-mutated copy may cause different, milder, or no symptoms of a sex-linked disorder.

Shotgun Sequencing

Shotgun sequencing is a laboratory technique for determining the DNA sequence of an organism's genome. The method involves randomly breaking up the genome into small DNA fragments that are sequenced individually. A computer program looks for overlaps in the DNA sequences, using them to reassemble the fragments in their correct order to reconstitute the genome.

Single Nucleotide Polymorphism (SNP)

A single nucleotide polymorphism (abbreviated SNP, pronounced snip) is a genomic variant at a single base position in the DNA. Scientists study if and how SNPs in a genome influence health, disease, drug response and other traits.

Somatic Cells

Somatic cells are the cells in the body other than sperm and egg cells (which are called germ cells). In humans, somatic cells are diploid, meaning they contain two sets of chromosomes, one inherited from each parent. DNA mutations in somatic cells can affect an individual, but they cannot be passed on to their offspring.

Southern Blot

Southern blot analysis is a laboratory method used to study DNA. Specifically, purified DNA from a biological sample (such as blood or tissue) is digested with a restriction enzyme(s), and the resulting DNA fragments are separated by using an electric current to move them through a sieve-like gel or matrix, which allows smaller fragments move faster than larger fragments. The DNA fragments are transferred out of the gel or matrix onto a solid membrane, which is then exposed to a DNA probe labeled with a radioactive, fluorescent or chemical tag. The tag allows any DNA fragments containing complementary sequences with the DNA probe sequence to be visualized within the Southern blot. The method is named for its creator, British molecular biologist Edwin Southern.

Stop Codon
A stop codon is a sequence of three nucleotides (a trinucleotide) in DNA or messenger RNA (mRNA) that signals a halt to protein synthesis in the cell. There are 64 different trinucleotide codons: 61 specify amino acids and 3 are stop codons (i.e., UAA, UAG and UGA).

Substitution
Substitution, as related to genomics, is a type of mutation in which one nucleotide is replaced by a different nucleotide. The term can also refer to the replacement of one amino acid in a protein with a different amino acid.

Susceptibility
Susceptibility, as related to genetics, refers to the state of being predisposed to, or sensitive to, developing a certain disease. An individual's disease susceptibility is influenced by a combination of genetic and environmental factors.

Syndrome
A syndrome, as related to genetics, is a group of traits or conditions that tend to occur together and characterize a recognizable disease. Some syndromes have a genetic cause.

-T-

Tandem Repeat
A tandem repeat is a sequence of two or more DNA bases that is repeated numerous times in a head-to-tail manner on a chromosome. Tandem repeats are generally present in non-coding DNA. In some cases, tandem repeats can serve as genetic markers to track inheritance in families. They can also be useful for DNA fingerprinting in forensic studies.

Telomere
A telomere is a region of repetitive DNA sequences at the end of a chromosome. Telomeres protect the ends of chromosomes from becoming frayed or tangled. Each time a cell divides, the telomeres become slightly shorter. Eventually, they become so short that the cell can no longer divide successfully, and the cell dies.

Thymine
Thymine (T) is one of the four nucleotide bases in DNA, with the other three being adenine (A), cytosine (C) and guanine (G). Within a double-stranded DNA molecule, thymine bases on one strand pair with adenine bases on the opposite strand. The sequence of the four nucleotide bases encodes DNA's information.

Trait
A trait, as related to genetics, is a specific characteristic of an individual. Traits can be determined by genes, environmental factors or by a combination of both. Traits can be qualitative (such as eye color) or quantitative (such as height or blood pressure). A given trait is part of an individual's overall phenotype.

Transcription
Transcription, as related to genomics, is the process of making an RNA copy of a gene's DNA sequence. This copy, called messenger RNA (mRNA), carries the gene's protein information encoded in DNA. In humans and other complex organisms, mRNA moves from the cell nucleus to the cell cytoplasm (watery interior), where it is used for synthesizing the encoded protein.

Transfer RNA (tRNA)
Transfer RNA (abbreviated tRNA) is a small RNA molecule that plays a key role in protein synthesis. Transfer RNA serves as a link (or adaptor) between the messenger RNA (mRNA) molecule and the growing chain of amino acids that make up a protein. Each time an amino acid is added to the chain, a specific tRNA pairs with its complementary sequence on the mRNA molecule, ensuring that the appropriate amino acid is inserted into the protein being synthesized.

Transgenic
Transgenic refers to an organism or cell whose genome has been altered by the introduction of one or more foreign DNA sequences from another species by artificial means. Transgenic organisms are generated in the laboratory for research purposes.

Translation
Translation, as related to genomics, is the process through which information encoded in messenger RNA (mRNA) directs the addition of amino acids during protein synthesis. Translation takes place on ribosomes in the cell cytoplasm, where mRNA is read and translated into the string of amino acid chains that make up the synthesized protein.

Translocation
A translocation, as related to genetics, occurs when a chromosome breaks and the (typically two) fragmented pieces re-attach to different chromosomes. The detection of chromosomal translocations can be important for the diagnosis of certain genetic diseases and disorders.

Tumor Suppressor Gene
A tumor suppressor gene encodes a protein that acts to regulate cell division, keeping it in check. When a tumor suppressor gene is inactivated by a mutation, the protein it encodes is not produced or does not function properly, and as a result, uncontrolled cell division may occur. Such mutations may contribute to the development of a cancer.

-U-

Uracil
Uracil (U) is one of the four nucleotide bases in RNA, with the other three being adenine (A), cytosine (C) and guanine (G). In RNA, uracil pairs with adenine. In a DNA molecule, the nucleotide thymine (T) is used in place of uracil.

-V-

Variant of Uncertain Significance (VUS)
When analysis of a patient’s genome identifies a variant, but it is unclear whether that variant is actually connected to a health condition, the finding is called a variant of uncertain significance (abbreviated VUS). In many cases, these variants are so rare in the population that little information is available about them. Typically, more information is required to determine if the variant is disease related. Such information may include more extensive population data, functional studies, and tracing the variant in other family members who have or do not have the same health condition.

Vector
A vector, as related to molecular biology, is a DNA molecule (often plasmid or virus) that is used as a vehicle to carry a particular DNA segment into a host cell as part of a cloning or recombinant DNA technique. The vector typically assists in replicating and/or expressing the inserted DNA sequence inside the host cell.

Virus
A virus is an infectious microbe consisting of a segment of nucleic acid (either DNA or RNA) surrounded by a protein coat. A virus cannot replicate alone; instead, it must infect cells and use components of the host cell to make copies of itself. Often, a virus ends up killing the host cell in the process, causing damage to the host organism. Well-known examples of viruses causing human disease include AIDS, COVID-19, measles and smallpox.

-X-

X Chromosome

The X chromosome is one of the two sex chromosomes that are involved in sex determination. Humans and most other mammals have two sex chromosomes (X and Y) that in combination determine the sex of an individual. Females have two X chromosomes in their cells, while males have one X and one Y.

X-Linked

X-linked, as related to genetics, refers to characteristics or traits that are influenced by genes on the X chromosome. Humans and most other mammals have two sex chromosomes, X and Y. Females have two X chromosomes in their cells, while males have one X and one Y. In the case of an X-linked disease, it is usually males that are affected because they have a single copy of the X chromosome that carries the disease-causing mutation. In females, the presence of a second, non-mutated copy may cause different, milder, or no symptoms of a sex-linked disorder.

-Y-

Y Chromosome

The Y chromosome is one of the two sex chromosomes that are involved in sex determination. Humans and most other mammals have two sex chromosomes (X and Y) that in combination determine the sex of an individual. Females have two X chromosomes in their cells, while males have one X and one Y.

Although the potential for genomics to contribute to clinical care has long been anticipated, the pace of defining the risks and benefits of incorporating genomic findings into medical practice has been relatively slow. Several institutions have recently begun genomic medicine programs, encountering many of the same obstacles and developing the same solutions, often independently. Recognizing that successful early experiences can inform subsequent efforts, the National Human Genome Research Institute brought together a number of these groups to describe their ongoing projects and challenges, identify common infrastructure and research needs, and outline an implementation framework for investigating and introducing similar programs elsewhere. Chief among the challenges were limited evidence and consensus on which genomic variants were medically relevant; lack of reimbursement for genomically driven interventions; and burden to patients and clinicians of assaying, reporting, intervening, and following up genomic findings. Key infrastructure needs included an openly accessible knowledge base capturing sequence variants and their phenotypic associations and a framework for defining and cataloging clinically actionable variants. Multiple institutions are actively engaged in using genomic information in clinical care. Much of this work is being done in isolation and would benefit from more structured collaboration and sharing of best practices.

Genet Med advance online publication 10 January 2013

Key Words: medical genomics; practice standards

INTRODUCTION

The potential for genomics to contribute to clinical care has long been recognized, and many optimistic scenarios for clinical use of information about a patient's genome have been proposed.[1–3] The pace of realizing this potential has appeared slow to some,[4,5] although clinical adoption of scientific discoveries has been estimated to take up to 17 years[6] and a recent genetic example[7] required 18 years after the initial 1991 report.[8] Indeed, relatively robust genotype–phenotype associations for common, complex diseases only began to become available around 2005.[9] Yet several academic medical centers and integrated health systems have already begun programs for implementing genomic medicine, which we define here as using an individual patient's genotypic information in his or her clinical care. This definition encompasses both Mendelian and multigenic complex diseases, and at present probably focuses most on single Mendelian variants of large effect, although emphasis is expected to shift soon to assaying and using multiple variants simultaneously in clinical care. This is not only because of an expanding knowledge base but also because the logistic complexities and costs of assessing genomic variation on a large scale are approaching those of one-at-a-time testing of individual variants, permitting a more holistic approach to incorporating genomic findings into clinical care.

These initial and separate forays have encountered similar obstacles and developed many of the same nascent solutions,

often quite independently. In expectation that sharing of lessons learned in these efforts can facilitate broader and more effective implementation of genomic medicine, the National Human Genome Research Institute in collaboration with several leaders in this area (R.L.C., G.S.G., D.M.R., M.S.W., and R.Wilson) brought together about 20 groups working to implement genomic medicine for a Genomic Medicine Colloquium in June 2011. This article summarizes the projects described by these groups, describes challenges they have encountered in implementation, identifies common infrastructure and research needs, and outlines an implementation framework for introducing similar genomic medicine programs more broadly.

BRIEF LANDSCAPE OF GENOMIC MEDICINE PROJECTS

Participating sites reported a broad range of genomic medicine activities, both in pilot and full implementation forms (**Table 1**). These included genotyping (used here and throughout to refer to the detection of genetic variants by single-nucleotide polymorphism assay, sequencing, or other technologies) of somatic mutations in malignant tumors to guide treatment decisions. The expanding scope and growing acceptance of such techniques places tumor genotyping at the forefront of genotype-directed care. All the participating sites (and most cancer centers nationwide) conduct tumor genotyping of cancers such as melanoma and those of the breast, colon, and lung for the targeting of therapy. Several also use genotyping to select patients for interventional protocols, but the main focus here was on the use of genomics outside of cancer diagnosis and treatment.

Several centers have begun targeted screening for highly penetrant germline mutations for Lynch syndrome and in *BRCA1/2*[10–12] to identify genetically at-risk individuals. With appropriate immunohistochemical or other evidence suggestive of germline mutations, patients can be actively sought and counseled regarding the importance of genomic testing for their own treatment and for potential preventive care of their relatives. Direct outreach to patients at the Cleveland Clinic, for example, increased the uptake of germline testing in patients with colorectal cancer by nearly sixfold—from 14% with information provided directly to surgeons to 80% with a genetic counselor seeing patients at follow-up examinations (C.E., unpublished data). Highly penetrant variants such as these provide robust, evidence-based paradigms to help move a clinical site toward implementing broader genomic medicine approaches. More important, perhaps, successful implementation of screening programs at early adopter sites provides valuable lessons and refined approaches that may be adopted elsewhere.[13]

Table 1 Examples of genomic medicine projects currently in implementation at participating sites

Tumor-based genotype-driven treatment
Risk/susceptibility testing in relatives of patients with mutation-bearing cancer (Lynch syndrome, *BRCA1/2*, etc.)
Family history collection for assessment of individual risk
CYP2C19 and antiplatelet therapy
Other genotype-driven treatment decisions
Whole-genome/whole-exome sequencing for unknown disease diagnosis
Complex disease risk advice (myocardial infarction and type 2 diabetes)

Self-reported family history information can also be used in risk assessment for individual patients with documented clinical validity and utility,[14,15] despite its potential weaknesses such as incomplete or inaccurate reporting.[16] Family history is generally not difficult to collect, especially with electronic data collection tools such as the Surgeon General's My Family Health Portrait,[17] although integrating the information into an independent electronic medical record (EMR) is not trivial. Clinicians are generally familiar with family history and appreciate its importance, and evidence-based guidelines are available for several conditions.[12,14] A Duke University pilot project, for example, is collecting three-generation family history information on 48 diseases using a Web-based computerized tool.[18] Patient-entered information is integrated into the medical record and generates a pedigree, tabular family history, and reports for the patient and clinician, as well as decision support information for four conditions (breast, ovarian, and colorectal cancer and venous thrombosis). Outcomes being assessed include patient and clinician satisfaction and ease of use; changes in patient behaviors such as diet and smoking; changes in physician behaviors such as screening and referral; and estimates of sensitivity, specificity, net reclassification, and cost.[18] Similarly, a Cleveland Clinic prototype collects three-generation family histories for the assessment of all inherited cancer syndromes.[19] Intermountain Healthcare has also deployed a patient-entered family tool ("Our Family Health") in their electronic patient portal.[20]

Pharmacogenomics provides additional opportunities in genomic medicine, particularly if appropriate decision support tools present relevant data to clinicians only when needed. Patients genetically unable to activate prodrugs such as clopidogrel, tamoxifen, and codeine, for example, do not need their genetic data presented to their clinicians unless and until these drugs are about to be prescribed. Although "reactive" genotyping for pharmacogenomic variants can be ordered at many sites, turnaround is often slow and uptake low. To address this, the Vanderbilt University Medical Center and St. Jude Children's Research Hospital have both implemented programs to conduct preemptive genotyping in patients very likely to receive medications with relevant genetically based dosing algorithms. At Vanderbilt, for example, selected patients, including those undergoing coronary angiography for acute coronary syndromes receive genotyping on a 184-variant platform that includes *CYP2C19* alleles before being prescribed clopidogrel,[21] based on a review of available evidence of poorer outcomes in persons with variant *CYP2C19* alleles.[22–24] At St. Jude Children's Research Hospital, array-based testing for 225 genes is performed, and results for those genes with the strongest clinical evidence are placed in the EMR.[25] Clinical pharmacogenomic testing is expanding to several sites affiliated with the Pharmacogenomics Research Network (PGRN)[26] with a goal of implementing proactive genotyping of a large number of variants, such as those identified by PharmGKB[27] or the US Food and Drug Administration (FDA).[28]

Preemptive testing, embedding this information into the EMR with appropriate decision support, and then seamlessly presenting it at the point of care when needed, rather than requiring tests to be ordered each time a relevant medication is prescribed, could help to minimize delay, cost, lack of follow-through, and duplicate testing. This is a testable hypothesis and one that is likely to be explored in programs such as the Electronic Medical Records and Genomics (eMERGE) Network.[29] Preemptive pharmacogenomic information could be even more useful were informed patients able to access it and work proactively with their clinicians in making treatment decisions. Putting patients in control of their genomic information is another potential strategy for genomic medicine implementation that needs evaluation. Such implementation strategies could be evaluated by measuring improvement, or lack thereof, in efficiency, cost, and health outcomes.

Whole-exome (protein-coding exons plus other highly conserved regions) and whole-genome sequencing are beginning to be used for identifying genetic causes of rare, unknown conditions, particularly those presenting in childhood or in strongly affected pedigrees for which novel mutations are more easily detected.[30] The recent cases of a young boy with severe, atypical, refractory inflammatory bowel disease[31] and of three families with severe arterial calcifications[32] demonstrate the potential for this approach to detect novel disease-causing mutations and point the way toward appropriate therapies. The Medical College of Wisconsin and Children's Hospital of Wisconsin have implemented a genome sequencing program to which clinicians can nominate patients who remain undiagnosed after appropriate clinical evaluation and testing. Nominations are reviewed by a multidisciplinary patient selection committee chaired by the hospital's chief medical officer. Patients and their families undergo 6–8 h of assessment and counseling before enrollment. Sequencing is provided by a commercial laboratory certified by the College of American Pathologists (CAP) Laboratory Accreditation Program and the Clinical Laboratory Improvement Amendments (CLIA) Program. The detected variants are analyzed using an in-house, validated software package, focusing first on specific candidate genes nominated by the referring clinicians to limit the chances of incidental, potentially unrelated findings. Analysis is then broadened if initially nominated genes are uninformative. Potentially relevant variants are confirmed by an independent method, and those results are placed in the medical record. The Baylor College of Medicine has implemented a Whole Genome Laboratory[33] with "in-house" sequencing and analysis of variants in a CLIA/CAP environment with review and sign-out by a board-certified clinical molecular geneticist. A number of other centers (Geisinger Clinic, Partners Healthcare, Washington University) and commercial laboratories such as Ambry Genetics,[34] GeneDx,[35] and SeqWright[36] are also now offering whole-genome sequencing that can be used in clinical care.

These four briefly described applications—tumor-based screening, family history–directed decision support, pharmacogenomics, and diagnostic genome sequencing—demonstrate that genomic medicine is no longer on the threshold; it has arrived. Although much of this work is being pursued as part of research programs, some has been adopted institutionally and offered in a CLIA-certified laboratory environment as part of regular clinical care.[13] Evaluating the impact of such programs and expanding their reach to diverse settings and populations is a high priority within the National Human Genome Research Institute's research agenda and mission. Information from such programs is helping to provide a needed evidence base to support more widespread implementation and reimbursement. Consideration of the barriers encountered and strategies used to surmount them by "early adopter" genomic medicine sites may help speed their evaluation and facilitate their expansion to the mainstream of clinical care.

CHALLENGES IN IMPLEMENTATION

Numerous challenges and barriers have been encountered in launching genomic medicine projects and many common solutions have emerged (**Table 2**). The greatest challenge may be the lack of appreciation by clinicians, health-care institutions, and payers of the potential for genomics to improve patient care, as compelling evidence of clinical validity and utility is limited at present.[37] Even for genomic applications with proven validity and utility, such as family history, there is lack of adoption and implementation, suggesting the lack of evidence is far from being the only barrier.

Cost concerns and institutional inertia typically demand convincing arguments and hard data before clinical practice is changed, yet the genome-wide nature of results to be expected by incorporating dense genotyping technologies into clinical care will soon force clinicians and institutions to deal with genomic information for which evidence may be quite limited. Evidentiary thresholds may thus need to be aligned with the intended use of the information, as the impact of genotype-driven care on morbidity and mortality cannot be tested for every variant.

Institutions have frequently relied on expert panels and local committees to evaluate available evidence and recommend particular new initiatives in genomic medicine, such as testing for specific pharmacogenomic variants or estimating risk to carriers. Such panels have tended to work in isolation from institution to institution, surveying the same evidence and often coming to similar conclusions. Far better would be to harness the collective knowledge of these groups in a more systematic way, distributing among them the genomic medicine issues for which evidence is compiled and evaluated, such as antidepressant therapy, coronary disease risk assessment, or risk in relatives of patients with colorectal cancer. These groups could then use a mutually accepted protocol for evaluation, with conclusions of each process shared among all. This is similar to the approach taken by the Centers for Disease Control and Prevention's Evaluation of Genomic Applications in Practice and Prevention (EGAPP),[38]

Table 2 Challenges in implementation and potential solutions

Challenge	Potential solutions
Limited evidence and conflicting interpretation of benefit/value	Generate evidence of clinical utility of genomic medicine interventions
	Tailor needs for evidence against potential benefits and risks
	Convene expert panels to develop guidelines based on best available evidence
	Engage nonaffiliated community-based practices, where institutional resistance may be minimal, to assist in developing evidence
	Determine process outcomes of incorporating genomic information into EMRs
	Widely publicize successes
	Organize consortia to conduct multicenter trials of genotype-directed therapy when appropriate
Lack of institutional and clinician acceptance	Establish institutional advisory committee(s) involving senior leadership to evaluate evidence, recommend, and monitor implementation
	Engage early adopters and clinical champions in demonstration efforts
	Conduct pilot projects in early adopter clinical environments to develop results sufficient for follow-on funding
	Obtain transinstitutional commitment at highest levels involving all relevant departments and stakeholders
	Utilize internal pilot funding to catalyze initiation
	Build clinician acceptance of genetics professionals by judiciously integrating genetic counselors and/or geneticists in nongenetics clinical services throughout primary institution and affiliates
	Bring fragmented expertise for advancing genomic medicine under one transinstitutional center or institute
	Harness institutional quality improvement processes to assess and demonstrate value
Limited access to genomic medicine expertise and testing	Use research screening assays on site and confirm clinically actionable findings with rapid, cost-effective CLIA-certified testing off-site if necessary
	Establish or expand institutional CLIA-compliant genotyping to expand point-of-care testing, same-day service
	Choose platform to assay multiple important genotypes simultaneously, reliably, and cheaply
	Invest in new equipment and personnel to ensure research quality control is at the same level as the clinical laboratory; this requires an institutional investment
	Work with genetic counselors to establish protocol for process and parameters of data return
	Develop better justification and approaches for reimbursing efforts of clinicians and genetic counselors
	Assess and provide sufficient genetic counselor staff or ancillary staff
	Establish institutional genomic medicine interdisciplinary clinical case conference for discussion and guidance on difficult clinical cases
Lack of standards for genomic applications	Develop agreed-upon framework or standards for evaluation of genomic medicine applications
	Develop standardized order sets and process modification
	Develop standards for analytic validity of whole-genome and whole-exome sequencing sufficient for clinical application, and for interpretation of the variants found by these methods
EMR integration of genomic results and clinical decision support	Enable access to actionable genetic information in the EMR through development of user-friendly decision support algorithms for health-care providers
	Establish "Usability Lab" to assess CDS tools and minimize alert fatigue
	Allocate genomic medicine institutional funding to develop education and outreach to disseminate "best practices" incorporating family history and genomic information
	Redesign the EMR to include section dedicated to containing all relevant genotype results for a patient
	Develop and link actionable drug–gene pair decision support to electronic pharmaceutical ordering software at point of care to facilitate adoption of pharmacogenomic testing
	Establish interdisciplinary workgroup with genomic medicine and EMR team to create secure tools for EMR-based genomic decision support
Follow-up of genotyped patients	Shift from relying on primary physician contact to direct contact and follow-up by genomic medicine team, with permission of physician
	Analyze and address reasons for refusal to complete confirmatory testing, such as lack of coverage for testing
Outreach to at-risk family members	Clarify implications for family members and health-care providers' responsibilities towards family members
	Explore ways to improve information to at-risk family members
Consent	Ensure consents for implementation projects conducted as research studies include returning results to patients and entering results into medical record
	Conformance with standard of care and specific consent may not be needed
	Consider initial implementation projects that might not require consent, such as results in established clinical pathways (tumor mutations, *CYP2C19*2*)
	Develop standards for informed consent for extensive sequencing, including whole-genome sequencing, and obtain it prospectively
	Ensure that availability of personnel to manage consent/counseling is not rate limiting in initial implementation

CDS, clinical decision support; CLIA, Clinical Laboratory Improvement Amendments; EMR, electronic medical record.

Table 2 Continued on next page

Table 2 Continued

Challenge	Potential solutions
Understanding by patients, clinicians, public	Conduct focus groups of patients, clinicians, and ancillary personnel to identify specific educational needs
	Conduct genetic and genomic medicine education campaign for patients, clinicians, and ancillary personnel based on focus group input
	Survey retention of educational information by patients and clinicians and modify programs as needed
	Conduct genotyping and/or sequencing and interpretation exercises with medical and other health profession students
	Provide specific health-care provider education on when to order test, and how to interpret and how to act on implications for family members and provider's responsibilities
	Introduce pharmacogenomic lectures into health professionals' training and continuing education
	Provide clinical supervision to clinician trainees in use of pharmacogenomic testing, other genomic point-of-care testing
Lack of access to comparison "control" sequence data and banking resources	Combine current centers' small patient collections of "normal" sequences and make available to all
	Prioritize funding for costly and time-consuming storage of viable tissues
	Bank high-quality tumor samples for confirmatory clinical sequencing with patient identifiers
	High-level institutional commitment to combine and organize multiple biorepositories for efficiency and ease of access
Lack of research funding and reimbursement	Until evidence base is established for making genomic testing new standard of care, consider research funding for testing in interim between discovery and adoption
	Gradually change culture to convince health-care community and patients of value of genomic medicine and need for reimbursement
	Demonstrate cost of testing is not prohibitive and savings and impact can be substantial
	Provide institutional back-up for reimbursement to avoid charges to patients
	Anticipate rises in interpretive and delivery costs as technology cost drops and enthusiasm increases

CDS, clinical decision support; CLIA, Clinical Laboratory Improvement Amendments; EMR, electronic medical record.

the Clinical Pharmacogenomics Implementation Consortium,[39] and by some early adopter institutions in developing committees of their own. Given the rapid spread of diagnostic sequencing and direct-to-consumer testing, it may be appropriate to begin to identify an intermediate category of "actionable" variants, for which evidence is insufficient to establish unequivocal clinical utility but is sufficient to determine how already available information could be used. Consideration should be given to tailoring of required levels of evidence to the risk/benefit ratio of the specific clinical setting at issue; development of consensus on evidence needed in different scenarios would be a valuable contribution. Recommendations for drastic or irreversible interventions such as genotype-driven mastectomy or salpingo–oophorectomy, for instance, should require far stricter evidence than should low-risk interventions such as modifying choice between two proven, roughly equivalent medications such as codeine and hydromorphone.[40]

For more modest interventions, the risks are more likely to involve factors such as burden to clinicians and patients in obtaining, interpreting, and managing the result, including learning of incidental findings not sought by clinician or patient; cost of testing; and psychological impact of the information on patients or their families. The first two of these can be addressed in part by improving the accessibility and lowering the costs of obtaining genomic information suitable for clinical use, which is occurring rapidly with expanding certification of genomic technologies and laboratories under CLIA and CAP. Testing fees can be substantial, especially when individual genetic variants are assayed sequentially, and indeed are soon likely to rival the cost of obtaining an entire genome sequence.[41] For a genetically heterogeneous condition, such as Charcot-Marie-Tooth disease, that is potentially due to variation at one or more of over 40 genetic loci, for example, whole-exome sequencing can already be performed for less than half the price of the current clinically available "multigene panel."[42] Third-party reimbursement of these costs is thus crucial for ensuring uptake by institutions and patients.

Integrating effective clinical decision support tools into the EMR, to query a patient's genomic data as care is being delivered, will be needed to present relevant variants and recommendations only when they are indicated. Such real-time, genomically driven clinical decision support can help avoid "alert fatigue" and relieve the clinician of trying to sift through the massive amount of genomic information without impeding clinical workflow. Sharing the effort of following up actionable genetic variants and at-risk family members with a dedicated genomic medicine team, with the primary physician's agreement and in ways that do not "compete" for the patient, can also minimize burden on patients and clinicians and increase efficiency. Looking to the future, the potential to update EMRs automatically as new discoveries are made and their clinical utility validated provides exciting possibilities for rapid implementation of research advances. Growing knowledge and understanding, however, mean that variants that are today of uncertain importance may tomorrow be found to be of great clinical relevance and vice versa. The responsibility of the clinician to recontact the patient with this new information is uncertain and could pose a major burden as well as medico-legal risks.[43]

Psychological impact on patients and their families has traditionally been addressed by the informed consent process and genetic counseling, but expanding genomic medicine efforts will likely soon outstrip the available supply of genetic counselors.[44] Innovative models utilizing ancillary personnel or social media tools to provide counseling and education, along with broad-ranging educational campaigns to increase familiarity with genomic medicine among practitioners, patients, and payers, will have the greatest impact if they can be linked to early successes and readily observable local efforts.

Reports of successes such as reduced hospitalization rates following genotype-driven adjustments in warfarin dosing,[45] e.g., or symptomatic improvement or reduced adverse effects after genotype-driven selection of antidepressants,[46] can help stimulate discussion of the potential for genomic medicine to improve outcomes and shift an institution's culture to embrace genotype-guided care,[30] although even these examples need a more complete evidence base and remain controversial.[47–50]

INFRASTRUCTURE AND RESEARCH NEEDS

Genomic medicine programs share needs for basic informational and policy infrastructure as well as evidence and outcomes produced through research (**Table 3**). Key infrastructure needs include a comprehensive knowledge base that captures sequence variants and their phenotypic associations and is openly accessible to clinical groups attempting to interpret sequence data. Such a knowledge base would have enormous value for research as well, particularly to the degree that it entails a careful curation and consensus process to reduce error and promote consistency. Here again, many genomic medicine groups appear to be doing this in isolation, capturing and reviewing such information internally but finding themselves constrained in sharing it outside their institutions. The policy aspects of establishing such a knowledge base, ensuring the accuracy of associations to be reported within it, and providing wide access to it are far from trivial and involve patient privacy and confidentiality of health information. Linking to appropriate supporting evidence and providing frequent updates are also daunting tasks, given the rapid pace of discovery, but are tasks that could readily be distributed among collaborating groups.

Perhaps an even greater informational need addressable by data sharing among genomic medicine groups and other genome sequencing projects is the ability to determine whether a newly discovered variant has been reported before. This is

Table 3 Infrastructure and research needs

Infrastructure
Continuously updated knowledge base and look-up tables of sequence variants linked to clinical phenotypes, genotype–phenotype relationships, actionable variants, and supportive evidence
Reliable, standardized genotyping/sequencing platforms, reporting formats, and quality control
High-throughput, rapid, low-cost genotyping/sequencing in CAP/CLIA-certified environments, potentially concentrated in large service centers for sequencing and interpretation
Evidentiary standards for various types of genomic testing in collaboration with other agencies (FDA, CMS) as needed, including standards and criteria for reimbursement
Point-of-care educational information and clinical decision support
Genomic medicine training programs for physicians, pharmacists, nurses, and other clinicians
Slide sets, videos, seminars, and social media approaches to patient, public, and clinician education
Increased person-power: clinicians with genetics training and background, genomic medicine consultants, genetic counselors, and implementation scientists
Expanded EMR capabilities to incorporate family history information, interface with genomic data
Research
Evidence development, such as changes following genomic medicine implementation in:
Disease severity, progression, or incidence
At-risk persons (such as family members) identified
Patients' or family members' anxiety, quality of life, and access to care or insurance
Cost, compliance, and patient or clinician satisfaction
Comparative effectiveness research
Identification of actionable variants
Bioinformatic/analysis tools to facilitate making associations, identifying "actionability" or impact scores for specific variants
Procedures and resources for interpreting potential clinical relevance of "variants of unknown significance," such as clinical proteomic tests, RNA-splicing tests, and cell-based assays, to determine experimentally whether a novel variant might cause disease
Standardized consent permitting return of results, deposition in EMR, sharing of variant tables
Collaborative projects/network to pool resources, share approaches, identify best practices, and avoid duplication
Best practices for:
Implementation and dissemination
Defining and collecting outcomes of implementation, including process outcomes
Delivering WGS information to individual providers and patients
Clearinghouse of successful implementation projects

CAP, College of American Pathologists; CLIA, Clinical Laboratory Improvement Amendments; CMS, Centers for Medicare and Medicaid Services; EMR, electronic medical record; FDA, Food and Drug Administration; WGS, whole-genome sequencing.

currently done by surveying available large-scale databases, such as the 1000 Genomes Project,[51] the Exome Variant Server,[52] and local institutional catalogs, on the presumption that a patient with a very rare or undiagnosed condition likely has a private or even unique variant.[53] Interpretation can be difficult because these reference databases generally lack phenotypic information. Far better than individual small cohorts of sequenced patients would be to aggregate cohorts and make their data widely available to qualified clinicians and researchers. Sequence variants in these databases should also be linked to phenotypic information, when possible, rather than forcing the assumption that all available sequenced individuals are free of the disease under consideration. The recently initiated Centers for Mendelian Genomics[54,55] will identify variants responsible for a great number of rare disorders and make this information widely available, which should help in this regard. The nascent ClinVar database of the National Center for Biotechnology Information[56] and the International Standards for Cytogenomic Arrays database available in dbGaP and dbVar[57] are two open-access databases that can provide valuable phenotypic information associated with rare sequence variants and structural variation.

Placing all this information in a single queryable source, regardless of where the actual data reside, would be a substantial advance in interpreting the three million or more differences from the human reference sequence identifiable per individual.[58] Genomic sequencing, in contrast to genotyping microarray technology, reveals rare or even unique alleles lacking scientific literature support for physiological effects. Computational approaches to predicting function may need to be incorporated into clinical decision support methods in trying to determine the implications of such variants for clinical care. Such analyses would be greatly facilitated by standard formats for reporting the data produced by individual sequencing groups rather than expecting individual clinicians and clinical sites to handle and interpret multiple different formats. The Centers for Disease Control and Prevention are currently working to develop performance specifications for next-generation sequencing.[59] Access to accurate, low-cost genome sequencing in CAP/CLIA-certified environments will remain a major limiting factor in utilizing sequencing in clinical care across diverse settings. Provision of genome sequencing as a commodity service in national or regional hubs, including interpretation of potential clinical relevance of identified variants, could be a major advance.

Appropriate professional organizations that can develop genomic medicine practice guidelines, such as the American College of Medical Genetics and Genomics, the College of American Pathologists, and the Association of Molecular Pathologists, as well as regulatory agencies such as the FDA and Centers for Medicare and Medicaid Services, should be involved in developing evidentiary standards tailored to specific interventions under consideration and criteria for reimbursement. Targeted education for active practitioners should also be tailored to specific settings and delivered as succinctly as possible at the point of care for maximum uptake and value, whereas broader educational efforts can capture clinicians earlier in their training.[60] Fellowships in pharmacogenomics and genomic medicine will be needed to develop specialists (perhaps "clinical genomicists," akin to radiologists or pathologists) capable of interpreting patients' genomic information and advising clinicians on appropriate actions to be taken for a given set of variants in a given clinical setting. Given the broad range of possible genomic medicine applications, the training of physicians and scientists enrolled in certified programs of the American Board of Medical Genetics and Genomics and the American Board of Pathology in clinical genetics, molecular genetics, biochemical genetics, and cytogenetics is particularly relevant. Consideration should be given to the potential for expanding the curricula of these programs to include more genomic medicine content or providing fellowships within these specialties that focus on genomic medicine.

Other educational modes such as seminars, slide sets, webinars, and videos need to be developed and shared across institutions doing similar types of work. Expanded EMR capabilities to permit querying of sequence or other dense genomic data, and incorporation of family history, are readily addressable. EMRs also have the ability to deliver context-specific educational information at the point of care during an eminently teachable moment, with a clinical conundrum at hand, as well as more sophisticated clinical decision support to aid clinicians in the appropriate use of genomic information.[61] Challenges in implementing point-of-care tools need to be recognized, however, including the potential for overwhelming clinicians with alerts leading to alert fatigue.[62] Here again, consideration should be given to the evidence needed for implementing such tools in genomic medicine and for ensuring the consistent adoption of point-of-care interventions for high priority health-care targets with the best risk/benefit ratio and strongest evidence, whether genomic or nongenomic.

Research is acutely needed to generate, collect, and make widely available the evidence needed for determining which variants are actionable, in whom, and in what clinical situations. Intermediate steps are needed that lie between genomic discovery research and routine clinical implementation to generate the evidence base to justify implementation. Consensus should be sought on the levels of evidence needed to justify the introduction of genomic medicine interventions, taking into account the degree of complexity or cost (such as family history vs. whole-genome sequencing) and risk/benefit (Lynch syndrome screening vs. universal colonscopy) involved, and the comparisons and outcome measures needed to answer these questions. Generating clear evidence of benefit for genomic interventions will remain challenging, however, in part because the rarity of many genomic markers of risk means large samples must be studied to accrue benefit/risk data in the small subsets of patients affected. Even with large samples, there can be controversy about the interpretation of the evidence, as shown by the data on the relationship between *CYP2C19* variants and failure of antiplatelet efficacy of clopidogrel.[63] In one meta-analysis that included only patients with acute coronary syndromes, there was strong evidence for an effect of variant alleles on outcomes,[23] whereas another analysis that included trials with different indications (and in which the efficacy of clopidogrel itself appears to be less) reported a much smaller effect of genetic variation on outcome.[24] Thus, the evidence supporting an effect of pharmacogenomic variants on variable drug outcomes may also depend on indication, substantially increasing the complexity of generating and evaluating evidence.

Research efforts should also aim to establish and validate criteria for actionability. They should facilitate association analysis and assessment of actionability and influence on outcomes from available data. Given that it is impossible, however, to perform prospective studies of the impact of all potentially important variants on clinical outcomes, comprehensive strategies will be needed to generate the necessary data. Real-world studies quantifying the impact of implementing genomic medicine programs on patient outcomes, cost and acceptability of care, and clinician and patient satisfaction are needed to promote adoption and dissemination of genomic medicine. Such studies fall under the rubric of "implementation research," defined as the study of methods to promote the systematic uptake of proven interventions into routine practice.[64] Comparative effectiveness research assessing the added value of genomic information, such as genomic variants added to family history added to clinical risk factors, and consensus on the outcomes and evidence needed to answer such questions, would help to define priorities for collecting and using such information in a cost-effective way.

Informed consents for genomic research should be broadened to include return of results, where desired and appropriate, so that lack of such consent (or indeed, consent forms declaring "no results will ever be returned") does not become an obstacle, if not an excuse, for failing to report actionable findings. The consent process should also explicitly address deposition of data in the EMR or research databases and sharing of variant information among researchers and clinicians.

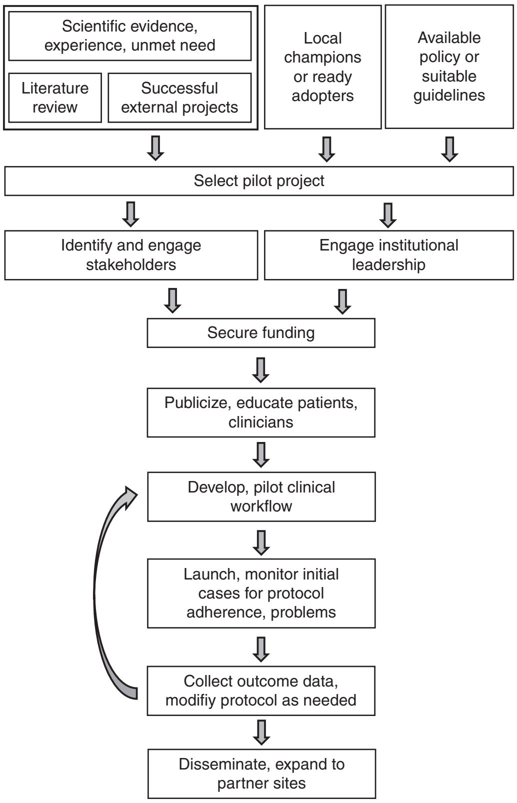
Assembling early adopters of genomic medicine into a confederation or community should facilitate addressing the many infrastructure and research needs outlined here. Collaborative projects such as those of the PGRN[65] can facilitate dissemination and testing of genomic medicine approaches in diverse settings to maximize their generalizability and usefulness. Such projects can help develop best practices for complex tasks such as implementation and dissemination, defining and collecting outcomes of implementation, and delivering genomic information to clinicians and patients. A clearinghouse of successful implementation projects, with detailed protocols addressing steps needed for patients, clinicians, laboratories, departments, and institutions, would go a long way toward disseminating this work beyond early adopter sites. Indeed, a critical question to ask is whether and how approaches developed at highly specialized and resourced tertiary care centers can be adopted in less resource-intensive settings.

IMPLEMENTATION ROADMAP

Incorporating genomic results into clinical care is as much a cultural and political exercise within a given institution as a scientific one, although a firm scientific grounding is essential to convincing the various stakeholders to accept an implementation project, particularly the first one (**Figure 1**). Such grounding can be obtained from a comprehensive review of the available scientific literature, recommendations of expert groups, and examination of ongoing successful projects at other institutions. Available policy or institutional guidelines on implementing changes to clinical care must also be considered. Critical in choosing an initial implementation project is the pragmatic issue of identifying a group of ready adopters or clinical champions, such as a subspecialty group or local practice, willing to try a new approach. Indeed, selection of a pilot project among several possibilities may hinge upon the availability of an enthusiastic group of clinicians.

Identifying and engaging the myriad stakeholders within an institution, including those needed to conduct genetic testing, interpret it, integrate it with the EMR, provide results and recommendations to the clinician, and pay for it, require that senior leaders who are familiar with the institution and its culture be on the genomic medicine team. It also often requires patience, persistence, and sufficient standing within the organization to convince skeptics and overcome institutional inertia. Some programs have found it simpler to begin at smaller affiliated hospitals or practices rather than at dominant academic medical centers.

Engagement and support from institutional leadership is obviously crucial, and most successful programs have involved



Scientific evidence, experience, unmet need
Literature review
Successful external projects
Local champions or ready adopters
Available policy or suitable guidelines
Select pilot project
Identify and engage stakeholders
Engage institutional leadership
Secure funding
Publicize, educate patients, clinicians
Develop, pilot clinical workflow
Launch, monitor initial cases for protocol adherence, problems
Collect outcome data, modifiy protocol as needed
Disseminate, expand to partner sites

Figure 1 Implementation roadmap: one approach to initial implementation at a single institution with subsequent evaluation and ultimately dissemination.

them directly in decision making, as chairs of committees selecting interventions to implement, for example, or evaluating their impact. Funding may be provided through local institutional support, in anticipation perhaps of eventual reimbursement by major payers, or through foundation or research funding, including National Institutes of Health–supported projects such as the Clinical Translational Science Awards and the PGRN. Institutional stakeholders are key in developing practical and efficient clinical workflows for obtaining testing and providing results. Development and testing of streamlined educational tools, which may be as simple as a pop-up window with appropriate links for the clinician and letters or brochures for patients, will be essential both for initiating a program and encouraging its acceptance. Once launched, careful monitoring of initial cases for adherence to established workflows and unanticipated barriers permits tailoring of procedures as needed. Outcome data related to ease of use, adherence, patient and clinician satisfaction and behaviors, cost, and, where possible, measures of morbidity and mortality can be used to modify the program and inform design and implementation of future efforts. Evaluation of the effectiveness of an implementation project should focus on outcomes of the implementation itself rather than the outcomes of treatment.[66] Several conceptual models for such evaluations are available for consideration.[67,68]

CONCLUSION

Multiple institutions are actively engaged in using patients' genomic information in their clinical care, either as pilot demonstration and research projects or as part of clinical care as a reimbursable service. The Genomic Medicine Colloquium revealed that much of this work is being done in isolation and would benefit from more structured collaboration and sharing of approaches across groups and institutions. Implementation of genomics in medicine would also benefit from establishing common infrastructure, such as a catalog of variants observed across large numbers of sequenced individuals to date, an updatable database of actionable variants, evidentiary standards tailored to benefits and risks, common clinical decision support tools including point-of-care educational materials, and collaborative projects to pool resources and identify best practices. Systematic and timely incorporation of advances in genomic research related to somatic and germline DNA, as well as consideration of RNA, protein, and epigenomic applications, will also be needed. The National Human Genome Research Institute, in collaboration with several other National Institutes of Health institutes and in accord with its recent strategic plan,[69] is currently exploring approaches for facilitating the research needed to implement genomic medicine on an ever-widening scale. Such efforts should also take full advantage of the extant momentum, information, and experience of "early adopters" across the United States, as well as the tools of implementation science to address the cultural barriers described above.

The substantial National Institutes of Health investment in basic genomic research has yielded and will continue to yield new insights into the role of genetic variants in health and disease. It is now time to ensure those results are translated and used to the maximum benefit of patients by periodically convening relevant stakeholders and building on the vanguard of nationwide genomic medicine implementation projects. Bringing these groups together in this way is anticipated to increase their diffusion, efficiency, and, ultimately, their value to patients and health care.

ACKNOWLEDGMENTS

This article summarizes the deliberations of a colloquium convened by the National Human Genome Research Institute on 29 June 2011 to examine opportunities and barriers for implementing genomic medicine in clinical care. The authors gratefully acknowledge the contributions of Gary Gibbons to the workshop.

DISCLOSURE

C.E. is an unpaid member of the External Scientific Advisory Board of MyMercury.com and of the Genomic Medicine Advisory Board of Complete Genomics, Inc. The other authors declare no conflict of interest.

Abstract: This commentary offers discussion on the pros and cons of universal healthcare in the United States. Disadvantages of universal healthcare include significant upfront costs and logistical challenges. On the other hand, universal healthcare may lead to a healthier populace, and thus, in the long-term, help to mitigate the economic costs of an unhealthy nation. In particular, substantial health disparities exist in the United States, with low socio–economic status segments of the population subject to decreased access to quality healthcare and increased risk of non-communicable chronic conditions such as obesity and type II diabetes, among other determinants of poor health. While the implementation of universal healthcare would be complicated and challenging, we argue that shifting from a market-based system to a universal healthcare system is necessary. Universal healthcare will better facilitate and encourage sustainable, preventive health practices and be more advantageous for the long-term public health and economy of the United States.

Keywords: chronic disease; health insurance; socio–economic status; obesity; diabetes; hypertension; health promotion; universal healthcare

1. Introduction

Healthcare is one of the most significant socio–political topics in the United States (U.S.), and citizens currently rank "healthcare" as the most important issue when it comes to voting [1]. The U.S. has historically utilized a mixed public/private approach to healthcare. In this approach, citizens or businesses can obtain health insurance from private (e.g., Blue Cross Blue Shield, Kaiser Permanente) insurance companies, while individuals may also qualify for public (e.g., Medicaid, Medicare, Veteran's Affairs), government-subsidized health insurance. In contrast, the vast majority of post-industrial, Westernized nations have used various approaches to provide entirely or largely governmentally subsidized, universal healthcare to all citizens regardless of socio–economic status (SES), employment status, or ability to pay. The World Health Organization defines universal healthcare as "ensuring that all people have access to needed health services (including prevention, promotion, treatment, rehabilitation and palliation) of sufficient quality to be effective while also ensuring that the use of these services does not expose the user the financial hardship" [2]. Importantly, the Obama-era passage of the Affordable Care Act (ACA) sought to move the U.S. closer to universal healthcare by expanding health coverage for millions of Americans (e.g., via Medicaid expansion, launch of health insurance marketplaces for private coverage) including for citizens across income levels, age, race, and ethnicity.

Differing versions of universal healthcare are possible. The United Kingdom's National Health Services can be considered a fairly traditional version of universal healthcare with few options for, and minimal use of, privatized care [3]. On the other hand, European countries like Switzerland, the Netherlands, and Germany have utilized a blended system with substantial government and market-based components [4,5]. For example, Germany uses a multi-payer healthcare system in which subsidized health care is widely available for low-income citizens, yet private options—which provide the same quality and level of care as the subsidized option—are also available to higher income individuals. Thus, universal healthcare does not necessarily preclude the role of private providers within the healthcare system, but rather ensures that equity and effectiveness of care at population and individual levels are a reference and expectation for the system as a whole. In line with this, versions of universal healthcare have been implemented by countries with diverse political backgrounds (e.g., not limited to traditionally "socialist/liberal" countries), including some with very high degrees of economic freedom [6,7].

Determining the degree to which a nation's healthcare is "universal" is complex and is not a "black and white" issue. For example, government backing, public will, and basic financing structure, among many other factors must be extensively considered. While an in-depth analysis of each of these factors is beyond the scope of this commentary, there are clear advantages and disadvantages to purely private, market-based, and governmental, universal approaches to healthcare, as well as for policies that lie somewhere in-between. This opinion piece will highlight arguments for and against universal healthcare in the U.S., followed by the authors' stance on this issue and concluding remarks.

2. Argument against Universal Healthcare

Though the majority of post-industrial Westernized nations employ a universal healthcare model, few—if any—of these nations are as geographically large, populous, or ethnically/racially diverse as the U.S. Different regions in the U.S. are defined by distinct cultural identities, citizens have unique religious and political values, and the populace spans the socio–economic spectrum. Moreover, heterogenous climates and population densities confer different health needs and challenges across the U.S. [8]. Thus, critics of universal healthcare in the U.S. argue that implementation would not be as feasible—organizationally or financially—as other developed nations [9]. There is indeed agreement that realization of universal healthcare in the U.S. would necessitate significant upfront costs [10]. These costs would include those related to: (i) physical and technological infrastructural changes to the healthcare system, including at the government level (i.e., federal, state, local) as well as the level of the provider (e.g., hospital, out-patient clinic, pharmacy, etc.); (ii) insuring/treating a significant, previously uninsured, and largely unhealthy segment of the population; and (iii) expansion of the range of services provided (e.g., dental, vision, hearing) [10].

The cost of a universal healthcare system would depend on its structure, benefit levels, and extent of coverage. However, most proposals would entail increased federal taxes, at least for higher earners [4,11,12]. One proposal for universal healthcare recently pushed included options such as a 7.5% payroll tax plus a 4% income tax on all Americans, with higher-income citizens subjected to higher taxes [13]. However, outside projections suggest that these tax proposals would not be sufficient to fund this plan. In terms of the national economic toll, cost estimations of this proposal range from USD 32 to 44 trillion across 10 years, while deficit estimations range from USD 1.1 to 2.1 trillion per year [14].

Beyond individual and federal costs, other common arguments against universal healthcare include the potential for general system inefficiency, including lengthy wait-times for patients and a hampering of medical entrepreneurship and innovation [3,12,15,16]. Such critiques are not new, as exemplified by rhetoric surrounding the Clinton Administration's Health Security Act which was labeled as "government meddling" in medical care that would result in "big government inefficiency" [12,15]. The ACA has been met with similar resistance and bombast (e.g., the "repeal and replace" right-leaning rallying cry) as a result of perceived inefficiency and unwanted government involvement. As an example of lengthy wait times associated with universal coverage, in 2017 Canadians were on waiting lists for an estimated 1,040,791 procedures, and the median wait time for arthroplastic surgery was 20–52 weeks [17]. Similarly, average waiting time for elective hospital-based care in the United Kingdom is 46 days, while some patients wait over a year (3). Increased wait times in the U.S. would likely occur—at least in the short term—as a result of a steep rise in the number of primary and emergency care visits (due to eliminating the financial barrier to seek care), as well as general wastefulness, inefficiency, and disorganization that is often associated with bureaucratic, government-run agencies.

3. Argument for Universal Healthcare

Universal healthcare in the U.S., which may or may not include private market-based options, offer several noteworthy advantages compared to exclusive systems with inequitable access to quality care including: (i) addressing the growing chronic disease crisis; (ii) mitigating the economic costs associated with said crisis; (iii) reducing the vast health disparities that exist between differing SES segments of the population; and (iv) increasing opportunities for preventive health initiatives [18–21]. Perhaps the most striking advantage of a universal healthcare system in the U.S. is the potential to address the epidemic level of non-communicable chronic diseases such as cardiovascular diseases, type II diabetes, and obesity, all of which strain the national economy [22,23]. The economic strain associated with an unhealthy population is particularly evident among low SES individuals. Having a low SES is associated with many unfavorable health determinants, including decreased access to, and quality of health insurance which impact health outcomes and life expectancies [24]. Thus, the low SES segments of the population are in most need of accessible, quality health insurance, and economic strain results from an unhealthy and uninsured low SES [25,26]. For example, diabetics with low SES have a greater mortality risk than diabetics with higher SES, and the uninsured diabetic population is responsible for 55% more emergency room visits each year than their insured diabetic counterparts [27,28]. Like diabetes, hypertension—the leading risk factor for death worldwide [29], has a much higher prevalence among low SES populations [30]. It is estimated that individuals with uncontrolled hypertension have more than USD 2000 greater annual healthcare costs than their normotensive counterparts [31]. Lastly, the incidence of obesity is also much greater among low SES populations [32]. The costs of obesity in the U.S., when limited to lost productivity alone, have been projected to equate to USD 66 billion annually [33]. Accessible, affordable healthcare may enable earlier intervention to prevent—or limit risk associated with—non-communicable chronic diseases, improve the overall public health of the U.S., and decrease the economic strain associated with an unhealthy low-SES.

Preventive Initiatives within A Universal Healthcare Model

Beyond providing insurance coverage for a substantial, uninsured, and largely unhealthy segment of society—and thereby reducing disparities and unequal access to care among all segments of the population—there is great potential for universal healthcare models to embrace value-based care [4,20,34]. Value-based care can be thought of as appropriate and affordable care (tackling wastes), and integration of services and systems of care (i.e., hospital, primary, public health), including preventive care that considers the long-term health and economy of a nation [34,35]. In line with this, the ACA has worked in parallel with population-level health programs such as the Healthy People Initiative by targeting modifiable determinants of health including physical activity, obesity, and environmental quality, among others [36]. Given that a universal healthcare plan would force the government to pay for costly care and treatments related to complications resulting from preventable, non-communicable chronic diseases, the government may be more incentivized to (i) offer primary prevention of chronic disease risk prior to the onset of irreversible complications, and (ii) promote wide-spread preventive efforts across multiple societal domains. It is also worth acknowledging here that the national public health response to the novel Coronavirus-19 virus is a salient and striking contemporary example of a situation in which there continues to be a need to expeditiously coordinate multiple levels of policy, care, and prevention.

Preventive measures lessen costs associated with an uninsured and/or unhealthy population [37]. For example, investing USD 10 per person annually in community-based programs aimed at combatting physical inactivity, poor nutrition, and smoking in the U.S. could save more than USD 16 billion annually within five years, equating to a return of USD 5.60 for every dollar spent [38]. Another recent analysis suggests that if 18% more U.S. elementary-school children participated in 25 min of physical activity three times per week, savings attributed to medical costs and productivity would amount to USD 21.9 billion over their lifetime [39]. Additionally, simple behavioral changes can have major clinical implications. For example, simply brisk walking for 30 min per day (≥15 MET-hours/week) has been associated with a 50% reduction in type II diabetes [40]. While universal healthcare does not necessarily mean that health policies supporting prevention will be enacted, it may be more likely to promote healthy (i) lifestyle behaviors (e.g., physical activity), (ii) environmental factors (e.g., safe, green spaces in low and middle-income communities), and (iii.) policies (e.g., banning sweetened beverages in public schools) compared to a non-inclusive system [34–36].

Nordic nations provide an example of inclusive healthcare coupled with multi-layered preventive efforts [41]. In this model, all citizens are given the same comprehensive healthcare while social determinants of health are targeted. This includes "mobilizing and coordinating a large number of players in society," which encourages cooperation among "players" including municipal political bodies, voluntary organizations, and educational institutions [41]. Developmental and infrastructural contributions from multiple segments of society to a healthcare system may also better encourage government accountability compared to a system in which a select group of private insurers and citizens are the only "stakeholders." Coordinated efforts on various non-insurance-related fronts have focused on obesity, mental health, and physical activity [41]. Such coordinated efforts within the Nordic model have translated to positive health outcomes. For example, the Healthcare Access and Quality (HAQ) Index provides an overall score of 0–100 (0 being the worst) for healthcare access and quality across 195 countries and reflects rates of 32 preventable causes of death. Nordic nations had an average HAQ score of 95.4, with four of the five nations achieving scores within the top 10 worldwide [42]. Though far more heterogenous compared to Nordic nations, (e.g., culturally, geographically, racially, etc.), the U.S. had a score of 89 (29th overall) [42]. To provide further context, other industrialized nations, which are more comparable to the U.S. than Nordic nations, also ranked higher than the U.S. including Germany (92, 19th overall), Canada (94, 14th overall), Switzerland (96, 7th overall), and the Netherlands (96, 3rd overall) [42].

4. Conclusions

Non-inclusive, inequitable systems limit quality healthcare access to those who can afford it or have employer-sponsored insurance. These policies exacerbate health disparities by failing to prioritize preventive measures at the environmental, policy, and individual level. Low SES segments of the population are particularly vulnerable within a healthcare system that does not prioritize affordable care for all or address important determinants of health. Failing to prioritize comprehensive, affordable health insurance for all members of society and straying further from prevention will harm the health and economy of the U.S. While there are undoubtedly great economic costs associated with universal healthcare in the U.S., we argue that in the long-run, these costs will be worthwhile, and will eventually be offset by a healthier populace whose health is less economically burdensome. Passing of the Obama-era ACA was a positive step forward as evident by the decline in uninsured U.S. citizens (estimated 7–16.4 million) and Medicare's lower rate of spending following the legislation [43]. The U.S. must resist the current political efforts to dislodge the inclusive tenets of the Affordable Care Act. Again, this is not to suggest that universal healthcare will be a cure-all, as social determinants of health must also be addressed. However, addressing these determinants will take time and universal healthcare for all U.S. citizens is needed now. Only through universal and inclusive healthcare will we be able to pave an economically sustainable path towards true public health.

Author Contributions: Conceptualization, G.Z., Z.Y.K., J.B.M., and L.S.; writing-original draft preparation, G.Z.; writing-review and editing, Z.Y.K., J.B.M., and L.S.; supervision, L.S. All authors have read and agreed to the published version of the manuscript.

Abstract

Genomic information about *Clostridium tetani*, the causative agent of the tetanus disease, is scarce. The genome of strain E88, a strain used in vaccine production, was sequenced about 10 years ago. One additional genome (strain 12124569) has recently been released. Here we report three new genomes of *C. tetani* and describe major differences among all five *C. tetani* genomes. They all harbor tetanus-toxin-encoding plasmids that contain highly conserved genes for TeNT (tetanus toxin), TetR (transcriptional regulator of TeNT) and ColT (collagenase), but substantially differ in other plasmid regions. The chromosomes share a large core genome that contains about 85% of all genes of a given chromosome. The non-core chromosome comprises mainly prophage-like genomic regions and genes encoding environmental interaction and defense functions (e.g. surface proteins, restriction-modification systems, toxin-antitoxin systems, CRISPR/Cas systems) and other fitness functions (e.g. transport systems, metabolic activities). This new genome information will help to assess the level of genome plasticity of the species *C. tetani* and provide the basis for detailed comparative studies.

Keywords: Clostridium tetani; Tetanus neurotoxin; Genomics; Plasmid

1. Introduction

Clostridium tetani is a Gram-positive, spore-forming and anaerobic rod-shaped bacterium which produces a potent neurotoxin, the tetanus toxin (TeNT). *C. tetani* forms spores which appear as translucent terminal enlargements having the general appearance of drumsticks. Spores are resistant to desiccation, heat and exposure to oxygen, and thus *C. tetani* can survive in environments such as soil for long periods of time [1]. More rarely, *C. tetani* can be found in the intestinal flora of animals and humans. Usually, *C. tetani* enters an organism through an open wound. Spores germinate and *C. tetani* grow in anaerobic conditions in necrotic tissues. TeNT is synthesized at the end of exponential growth and is released in the surrounding tissues. TeNT enters motorneurons and is retrogradely transported to the central nervous system. Then, TeNT enters inhibitory interneurons and blocks the release of neurotransmitters (glycine, GABA) upon proteolytic cleavage of the SNARE protein VAMP2 [2,3]. TeNT is responsible for all the symptoms of tetanus, characterized by spastic paralysis (muscle rigidity and spasms) [4]. In contrast to *botulinum* neurotoxins (BoNT), which show wide genetic diversity (see companion articles in this issue), only one TeNT type has been reported until now. It is presumed that *C. tetani* strains exhibit limited genetic variability. A previous study conducted via DNA/DNA hybridization showed that 10 neurotoxigenic and 3 non-toxigenic *C. tetani* strains were homogeneous [5]. At least two genetic profiles have been evidenced

in five *C. tetani* strains, as tested by pulse field gel electrophoresis [6]. It was first demonstrated that the *tent* gene is located on a large size plasmid and that the loss of this plasmid yields non-toxigenic strains [7]. The first complete genome sequence of a toxigenic *C. tetani* strain (E88) was determined in 2003 [8]. The genome contained a chromosome of approximately 2.8 Mb and the tetanus-toxin-encoding plasmid of 74 kb. One additional *C. tetani* genome was determined in 2014 [9]. Here we report the genome sequences of three additional *C. tetani* strains. We performed comparative genome studies in order to define the core and flexible genome content of *C. tetani*.

2. Materials and methods

2.1. Bacterial strains

The three *C. tetani* strains used for this study were CN655, 184.08 and strain A. Strain CN655 is a collection strain from Prevot's collection (Institut Pasteur) that originated from the Wellcome Institute (1947). Strain 184.08 was isolated from a suppurative arthritis case subsequent to a traumatism in a 75-year-old man in the south of France in 2008. Strain A is a variant of the Harvard strain.

C. tetani strains were grown in TGY broth (pH 7.5) containing trypticase (trypticase-glucose yeast peptone BBL, BD Biosciences; 30 g/L), yeast extract (Bacto Yeast Extract, BD Biosciences; 20 g/L), glucose (5 g/L) and cysteine, HCl (0.5 g/L) under anaerobic conditions.

2.2. DNA extraction and genome sequencing

Genomic DNA from all strains of *C. tetani* was extracted and purified as previously described [10]. Draft sequences of the genomes were obtained by using Illumina/Solexa GAIIx machines at the Beijing Genomics Institute (BGI) (Shenzhen, China). The assembly of sequence reads was done using SOAPdenovo (version 1.05).

2.3. Sequence analysis

Automatic annotation of all contigs was done using RAST (http://rast.nmpdr.org/). To identify homologs in different strains, comparisons of all coding DNA sequences (CDS) were made using a protein sequence-based bidirectional BLAST approach (blastP version 2.2.18). Sequence homologies were only mentioned in this study for proteins with an amino acid identity of >25% and an overlap of the query and subject sequence of >75%. Genome representations were created by a DNA plotter (Sanger Institute).

2.4. Sequence accession

GenBank accession numbers for the draft genome sequences are JSWC00000000 for strain CN655, JSWD00000000 for strain 184.08 and JWIX00000000 for strain A.

3. Results and discussion

Genomes of neurotoxigenic clostridia have been sequenced. Whereas many genome sequences of *C. botulinum* have been determined in the last decade (over 10 completed genomes and more than 30 draft genomes), only two *C. tetani* genomes are available thus far. The first genome sequence of *C. tetani* was determined in 2003 [8]. Recently, the genome of strain 12124569 was sequenced, an isolate that caused a rare case of chronic osteitis [9]. We decided to obtain more information on the genomic diversity of *C. tetani* by sequencing three additional genomes, those of strains CN655, 184.08 and A. Strain 184.08 was isolated from a suppurative arthritis of a 75-year-old man in the south of France in 2008. CN655 is a collection strain from Prevot's collection (Institut Pasteur) that originated from the Wellcome Institute (1947). Strain A is a variant of a Harvard strain. All these strains produce the tetanus toxin as tested in a mouse bioassay (data not shown).

3.1. Tetanus-toxin-encoding plasmids

All five strains possess a tetanus-toxin-encoding plasmid. G + C content, size and number of coding sequences (CDS) vary slightly, with the exception of strain 12124569 that carries a considerably smaller plasmid (Table 1). Sequence comparison revealed that plasmids of strains E88, CN665 and A (hereafter named pE88, pCN665 and pA) are highly similar to each other (Fig. 1); in contrast, plasmids of strains 184.08 and 12124569 (named p184.08 and p12124569, respectively) strongly differ (Fig. 2). Bidirectional blast (BIBlast) comparison revealed the extent of sequence divergence (Supplemental Table 1). Several genes of pE88, pCN655 and pA are not present on p184.08 and p12124569, including a two-component system and an ABC transport system. In contrast, p184.08 contains additional genes, including a type III restriction-modification system, a phage integrase and a putative bacitracin resistance transport system (Supplemental table 1B).

The sequences of TeNT and collagenase ColT are highly conserved: TeNT of pE88, pCN655 and pA are 100% identical at the amino acid level and are 98% identical (1294/1315) to TeNT from strains 184.08 and 12124569. Similarly, ColT of pE88, pCN655 and pA are 100% identical and they are 97% (963/991) identical to ColT of p184.08. Other highly conserved proteins encoded by all five plasmids are the two

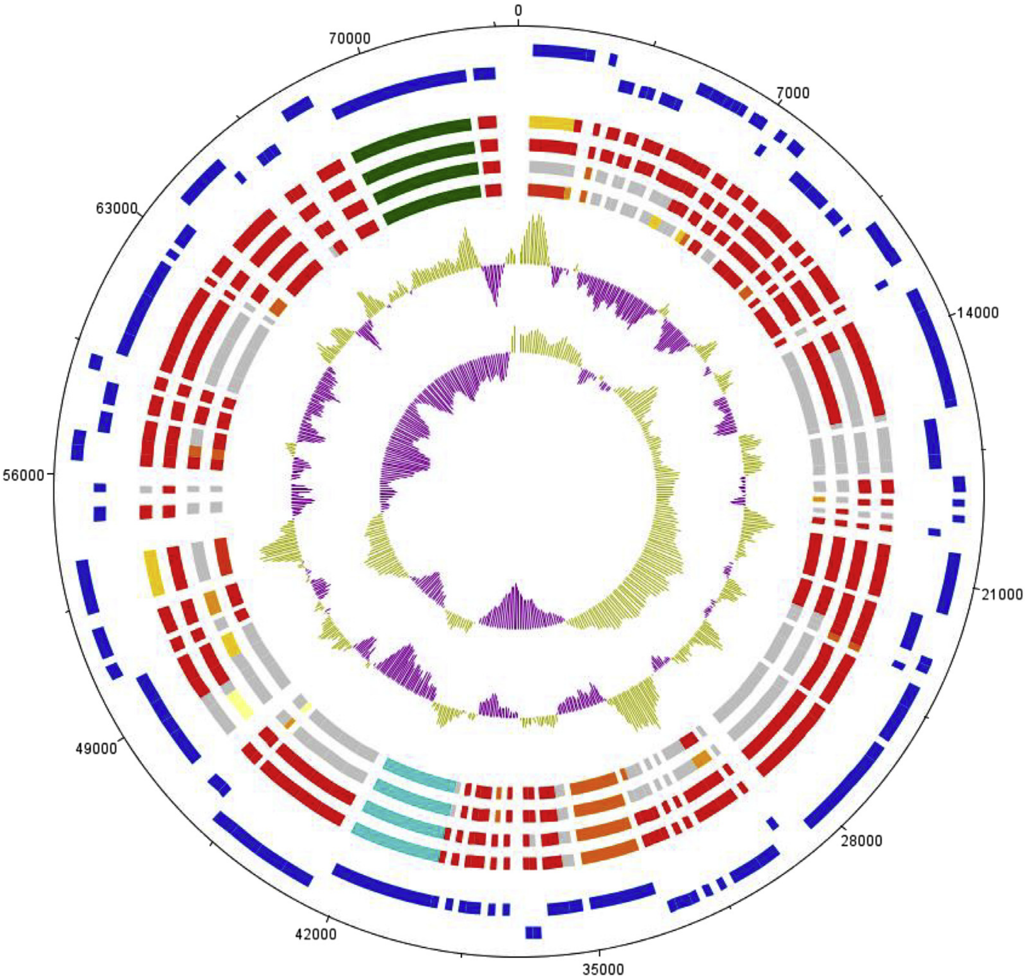

Fig. 1. A BiBlast-based comparison of five tetanus-toxin-encoding plasmids of *C. tetani* with pE88 as reference plasmid. The blue outer rings depict the CDS of pE88 (plus and minus strand); the four inner rings depict bidirectional Blast results regarding pCN655, pA, p12124569 and p184.08, respectively. Red: high similarity; orange: medium similarity; yellow: low similarity; gray: absence. The highly conserved tetanus toxin and collagenase genes are depicted in dark green and cyan, respectively. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.) two inner rings depict the G + C content and the G + C skew.

putative RNA polymerase sigma factors (CTP10 and CTP11 in pE88; 94% and 99% protein identity, respectively), an ABC transport system (CTP30/CTP31) and two putative aminopeptidases (CTP20 and CTP56 in pE88; 97% and 98% protein identity, respectively).

3.2. Chromosome of C. tetani

The chromosomes of the five *C. tetani* strains have a similar size (ca. 2.8 Mb) and G + C content (28.6–28.8%) (Table 2). They are highly conserved: the core genome comprises 85% and 83% of all CDS in strains E88 and 184.08, respectively, when applying a cutoff of 30% protein identity (Fig. 3). Even with a cutoff of 50% protein identity, 84% and 81.5% of all CDS of strains E88 and 184.08, respectively, belong to the core genome (Supplemental Table 2).

The majority of strain-specific functions are encoded in prophage regions. For example, the chromosome of strain E88 contains three strain-specific prophage regions (Supplemental Table 2). Other strain-specific functions include transposases (in particular, in the genome of E88), cell-surface/adhesion/S-layer proteins, restriction-modification-systems, ABC transport systems and efflux pumps, two-component systems, resistance determinants and defense/repair functions as well as specific metabolic functions. For instance, strains 184.08 and 12124569 contain peptide methionine sulfoxide reductase MsrB. Strain E88 specifically contains a plasmid-like locus comprising an adenine-specific methyltransferase and a toxin-antitoxin system. Regarding metabolic functions, for example, strain 184.08 possesses the genes for an allophanate hydrolase that converts allophanate to ammonium and carbon dioxide, an essential system for using urea as a nitrogen source.

Another difference between the strains concerns the clustered regularly interspaced short palindromic repeats (CRISPR)/Cas loci and the diversity of CRISPR spacers. The CRISPR/Cas system constitutes an adaptive immune system that protects the bacterium from bacteriophage infections and from mobile genetic elements. Strain E88 contains two loci:

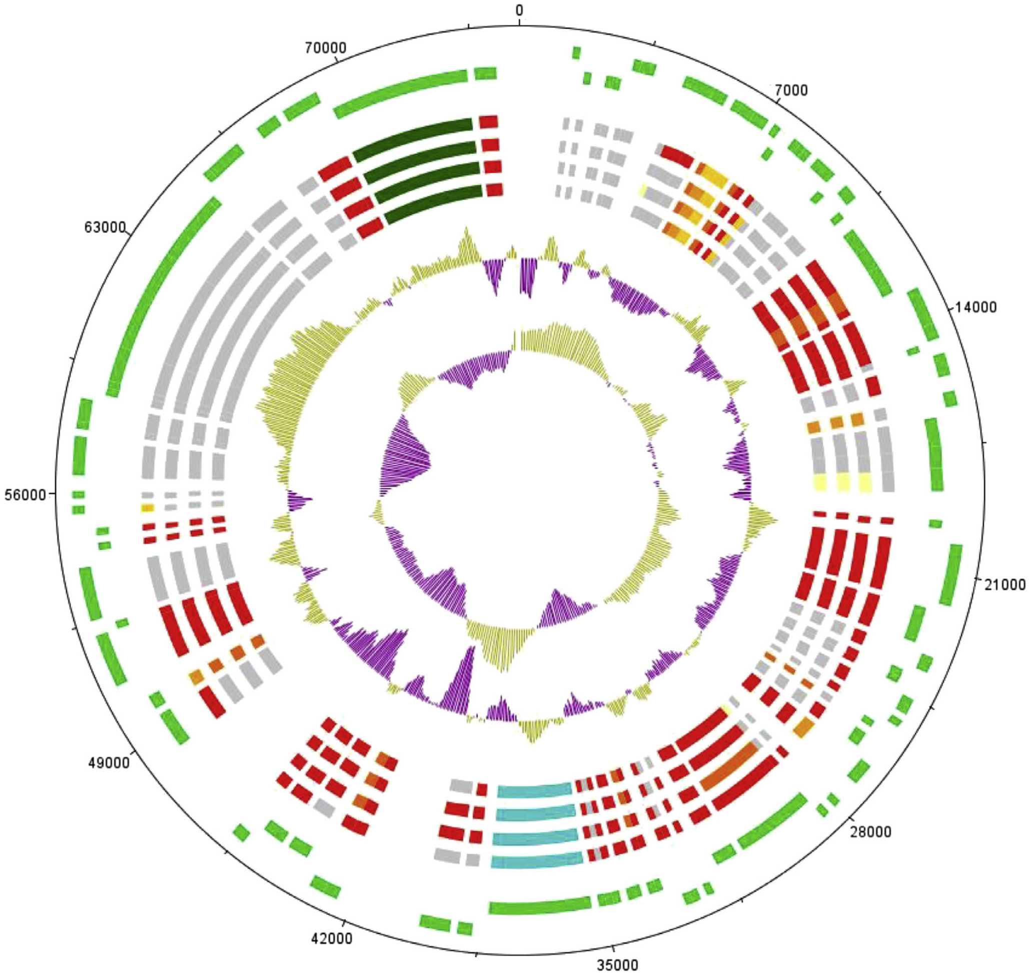

Fig. 2. A BiBlast-based comparison of five tetanus-toxin-encoding plasmids of *C. tetani* with p184.08 as reference plasmid. The green outer rings depict the CDS of p184.08 (plus and minus strand); the four inner rings depict BiBlast results regarding p12124569, pE88, pCN655 and pA, respectively. Red: high similarity; orange: medium similarity; yellow: low similarity; gray: absence. The highly conserved tetanus toxin and collagenase genes are depicted in dark green and cyan, respectively. The two inner rings depict the G + C content and the G + C skew. Please note that the map of p184.08 was reconstructed from 9 contigs aligned to pE88; thus, sequence gaps in p184.08 exist. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

one locus (CTC1142-CTC1148) is composed of the *cas* genes *cas6, csx8 (cas8a1), devR (cas7), cas5, cas3, cas4 and cas1* (type I-A-like system) with a repeat consensus 5′-GTATTAGTAGCACCATATTGGAATGTAAAT-3′ and the other one (CTC1463-CTC1469) is composed of *cas6, csh1 (cas8b), csh2 (cas7), cas5, cas3, cas4, cas1* and *cas2* (type I–B system) with a repeat consensus 5′-ATTTAAATACAACTCTTGTTATTGTTCAAC-3′. Most of the spacers (66 in strain E88) show no similarity to sequences deposited in databases. Some spacers match strain-specific prophage regions in other *C. tetani* and/or *C. botulinum* genomes. Interestingly, a number of spacers also match regions within the same genome: for example, spacers in E88 match E88 genomic regions encoding stage IV sporulation protein (CTC1140), sporulation sigma-E-factor-processing peptidase (CTC1125), vancomycin b-type resistance protein VanW (CTC0360) and S-layer protein/N-acetylmuramoyl-L-alanine amidase (CTC0462). This indicates that such regions are located on mobile genetic elements that have been acquired by horizontal gene transfer events. The type IA-like CRISPR/Cas system in strain 12124569 is associated with a different repeat (5′-AATTTACATTCCAATATGGTGCTACTAATAC-3′) and contains 22 spacers. Some of them match prophage-like genomic regions in *C. tetani* and *C. botulinum*. The genome of strain 184.08 does not contain any CRISPR/Cas region. Interestingly, this genome also contains more prophage-like genomic regions that account for its larger genome size

Table 2
Features of 5 chromosomes of *C. tetani* strains.

	Size	Contigs	G + C (%)	CDS[a]
E88	2799251	1	28.7	2736
CN655	ca. 2780622	111	28.6	2734
A	ca. 2754351	90	28.6	2704
12,124,569	2807472	1	28.8	2809
184.08	ca. 2841472	135	28.6	2826

[a] Based on RAST annotation (http://rast.nmpdr.org/).

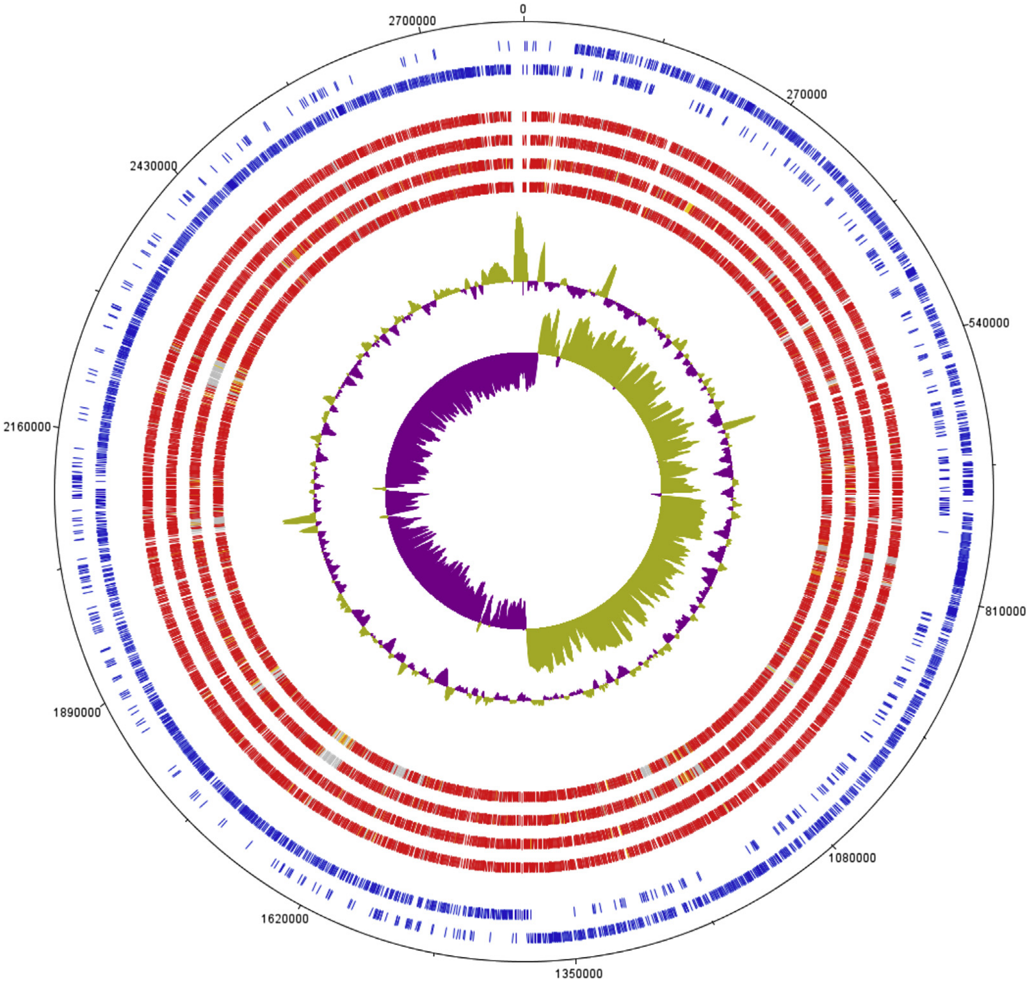

Fig. 3. A bidirectional blast comparison of the chromosomes of five *C. tetani* strains. The outer blue ring depict the CDS of reference strain E88; the inner four rings depict BiBlast results in the genomes of CN655, A, 12124569 and 184.08, respectively. Red: high similarity, orange: medium similarity, yellow: low similarity, gray: absence. The two inner rings depict G + C content and the G + C skew. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

compared to the other four *C. tetani* genomes (Table 2; Supplemental Table 2B). This indicates that the lack of CRISPR/Cas systems renders strain 184.08 more vulnerable to phage infections. The divergence of the CRISPR/Cas regions of *C. tetani* reflects the distinct bacteriophage infection history of each individual *C. tetani* strain.

In conclusion, genome comparison of *C. tetani* highlights flexible, non-core genome content. Larger islands within individual genomes often constitute prophage-like regions. Smaller genomic regions of divergence encode a set of fitness functions, increase competitiveness and protection and guarantee survival under stress conditions and attack, e.g. against bacteriophage infections.

The tetanus-toxin-encoding plasmids of the five isolates have several differences, underlying their highly flexible nature compared to the chromosome. In particular, plasmids of strains 184.08 and 12124569 differ significantly from pE88, the plasmid from the vaccine-producing strains E88 and A.

Conflict of interest

The authors have no conflict of interest.

ABSTRACT

Chickenpox (varicella) is caused by infection with the varicella-zoster virus (VZV), a neurotropic alpha herpes virus with a double-stranded DNA genome. Chickenpox can cause life-threatening complications, including subsequent bacterial infections, central nervous system symptoms, and even death without any risk factors. Few studies have been reported to investigate genetic susceptibility implicated in chickenpox. Herein, our study identified global genetic variants that potentially contributed to chickenpox susceptibility by utilizing the established bioinformatic-based approach. We integrated several databases, such as genome-wide association studies (GWAS) catalog, GTEx portal, HaploReg version 4.1, and Ensembl databases analyses to investigate susceptibility genes associated with chickenpox. Notably, increased expression of *HLA-S, HCG4P5*, and *ABHD16A* genes underlie enhanced chickenpox susceptibility in the European, American, and African populations. As compared to the Asian population, Europeans, Americans, and Africans have higher allele frequencies of the extant variants rs9266089, rs10947050, and rs79501286 from the susceptibility genes. Our study suggested that these susceptibility genes and associated genetic variants might play a critical role in chickenpox progression based on host genetics with clinical implications.

1. Introduction

Chickenpox, also known as varicella, is an infectious disease caused by the varicella-zoster virus (VZV) [1]. The VZV, also known as herpesvirus 3, is a type of alpha herpesvirus which has double-stranded Deoxyribonucleic Acid (DNA). The primary targets of VZV infection are T lymphocytes, ganglia, and epithelial cells [2]. The most common symptoms of chickenpox in children are fever, headache, backache, chills, nausea, and vomiting [3]. These symptoms are often accompanied by the appearance of a rash that spreads across the entire body's surface skin [4].

VZV infections occur globally, but the epidemiology of these infections varies by region depending on the geographical location. This infection typically occurs in tropical and subtropical regions. In temperate zones, the incidence of chickenpox infection is quite high during the winter and early summer [5]. The majority of individuals living in the United States and Great Britain have had chickenpox by age 15 [6]. In other temperate regions, such as Slovenia, three-to four-year-old children account for 75% of chickenpox infections [7]. In tropical and subtropical climates, adults are more frequently infected with varicella than children [8].

VZV DNA detection in blood and saliva are helpful for the diagnosis and prognosis of varicella/chickenpox infections. VZV DNA can be found in T cells after 10 days of rash and remains there a week after [9].

Fig. 1. Schematic of custom bioinformatics pipeline to identify chickenpox disease susceptibility genes across multiple continents. This figure was created with BioRender.com under agreement number "BH24OEAKNY ".

Variations in genes can aggravate chickenpox infection, but it is questionable whether they affect gene expression. Furthermore, a population with a high proportion of susceptibility gene carriers should be more susceptible to the disease.

To date, few studies have linked host genetic variation to chickenpox susceptibility [10]. As of this time, a previous study primarily focuses on the identification of the VZV genotype. The goal of the current study is to identify genetic variations that may contribute to Chickenpox disease transmission by utilizing bioinformatic-based approach. We integrated the genome-wide association studies (GWAS) catalog database with genomic datasets to identify gene expression associated with chickenpox. Therefore, our findings will provide the opportunity for future research to investigate whether these variants might be associated with different risks and susceptibility to chickenpox infection. Additionally, this discovery can be used to identify new candidate drugs for treating chickenpox disease.

2. Methods

A summary of the methodology of screening variants-associated with chickenpox disease is illustrated across the various steps in the bioinformatics pipeline (Fig. 1). We leveraged several bioinformatic-based approaches to integrate the variants of chickenpox disease, including GWAS catalog, GTEx portal, HaploReg version 4.1, and Ensembl databases. In the present study, the initial screening of Single Nucleotide Polymorphism (SNP) associated with chickenpox was obtained from the GWAS catalog database [https://www.ebi.ac.uk/gwas/] (accessed on August 19, 2022). We used the keyword "*chickenpox and susceptibility of chickenpox* "to obtain the GWAS-associated chickenpox. To determine the SNP associated with chickenpox, we strictly selected p-value $< 10^{-8}$ as inclusion criteria. In our analysis, we removed all duplicate variants from the dataset in order to guarantee these variants are unique SNPs. Subsequently, a bioinformatic-based approach was employed to interrogate the expression of these variants**.** Next, we validated the SNPs that had been rigorously filtered using the GTEx portal database [http://www.gtexportal.org/home/] (accessed on August 29, 2022). The purpose of this step is to evaluate these genetic variants with gene expression profiles in numerous body tissues. Following a search through the GTEx portal database, we further retrieved the SNPs encoded genes to identify the gene expression profiles. Herein, we leveraged the expression quantitative trait loci (eQTL) are regions harboring nucleotides correlated with alterations in gene expression. Therefore, the variants may cause changes in gene expression in the direction of the tissues involved (i.e., our analyses focused on the skin). Chickenpox is a highly contagious viral infection that causes a blistering, itchy rash on the skin accompanied by fever, viremia, and vesicular lesions that spread over the skin and are frequently reported in children [9]. We used Haploreg version 4.1 and Ensembl genomic databases to map the epidemiological distribution of the genetic basis of allele frequency in different populations. The allele frequencies associated with chickenpox were retrieved from a genetic database such as Haploreg version 4.1 [https://pubs.broadinstitute.org/mammals/haploreg/haploreg.php] (accessed on August 29, 2022) and Ensembl Genome Browser [http://www.ensembl.org/index.html] (accessed on August 30, 2022). Detection of the allele frequencies of each variant is intended to confirm the allele frequencies in populations from multiple continents (Africa, America, Asia, and Europe).

3. Results

Chickenpox-related SNPs were extracted from the GWAS catalog database. We identified 33 SNPs related to chickenpox that passed the inclusion criteria (Supplementary Table 1). Then, SNP data was filtered based on p-value $<10^{-8}$ and three SNPs were obtained related to

Table 1
Chickenpox associated Variant with criterion p-value $<10^{-8}$.

SNP	p-value	chr_pos
rs9266089	$1{,}00 \times 10^{-10}$	31352732
rs10947050	$1{,}00 \times 10^{-10}$	30072514
rs79501286	$2{,}00 \times 10^{-09}$	31475135

chickenpox (Table 1). Using the GTEx portal database, we later evaluated the tissue expression of three SNPs associated with chickenpox. This procedure is intended to verify that the three SNPs are closely associated with gene expression in skin tissues. Our study proposed that the SNPs, including rs9266089, rs10947050, and rs79501286 could affect the tissue expression of chickenpox.

4. Chickenpox gene expression in various tissues

We utilized the GTEx portal database in order to evaluate the expression of related genes in human tissues. This database focuses on the expression of eQTL in various human tissues, especially for the skin. The eQTL analysis could display gene expression data and describes the differences in gene expression caused by the tissue's natural genetic variations [10]. Intriguingly, the GTEx portal database identified three symbol genes associated with chickenpox, namely *HLA-S, HCG4P5*, and *ABHD16A* (Table 2), which exhibit gene expression in the skin. It is important to note that patients with chickenpox typically present with a rash and fever [9]. Therefore, our study focused on gene and variant expression in skin tissues.

5. *Cis*-eQTL of *HLA-S, HCG4P5,* and *ABHD16A genes* in skin tissue

In the present study, we utilized the GTEx portal database with the knowledge that the functional roles of these variants affect protein expression. The eQTL associated with chickenpox expression in skin tissue were identified using the GTEx portal database. Forty different gene variants demonstrated the expression in skin tissues. However, only three genes respectively demonstrated a dominant effect on the expression of *HLA-S* (Fig. 2A), *HCG4P5* (Fig. 2B), and *ABHD16A* (Fig. 2C) in the skin. Furthermore, an additional search using PubMed database text mining was conducted to investigate the three associated eQTL in the skin tissues to determine whether the genetic variants might have clinical significance.

6. Relationship between gene variation and gene expression in skin tissue

Using the publicly available GTEx portal database, we identified minor alleles of *HLA-S* rs9266089, *HCG4P5* rs10947050, and *ABHD16A* rs79501286 respectively associated with chickenpox. As shown in Table 2 and Fig. 3, the *HLA-S* rs9266089 AA genotype was associated with increased expression in skin tissue compared to the GA and GG genotypes. The *HCG4P5* rs10947050 TT genotype had a greater expression in the skin than the CT and CC genotypes. Meanwhile, the *ABHD16A* rs79501286 AA genotype had a higher expression in the skin than the GA and GG genotypes.

7. Allele frequencies of selected variants in different populations

The genetic basis of allele frequency of three genes *HLA-S*, *HCG4P5,* and *ABHD16A* expression and function in different populations is still largely unknown. Therefore, we determined allele frequencies from human populations across multiple continents after identifying chickenpox expression variations. Table 3 shows allele frequencies in African, American, Asian, and European populations. The above allele frequencies were obtained from the Haploreg version 4.1 database, available at https://pubs.broadinstitute.org/mammals/haploreg/haploreg.php (accessed on August 29, 2022). There was a variation in the allele frequencies across the population for each of the SNPs shown in Fig. 4, which were obtained from the Ensembl Genome Browser database http://www.ensembl.org/Homo_sapiens/Variation (accessed on August 30, 2022). Table 3 and Fig. 4 reveal the global allele frequencies for each SNP. The frequency of the A allele at rs9266089, which was associated with the highest expression of *HLA-S* in chickenpox, was significantly lower in Asian populations (2%) than in American (11%), African (10%), or European (15%) populations. T allele frequency showed a higher expression in *HCG4P5* rs10947050, whereas it showed much a lower expression in African (13%) populations compared to Asians (28%), Americans (23%), and Europeans (31%). The A allele of rs79501286 in *ABHD16A* was much less common in Africa (1%), Asia (1%), and America (4%), than in Europe (10%). The allele frequencies of *HLA-S* variant rs9266089, *HCG4P5* variant rs10947050, and *ABHD16A* variant rs79501286 indicated that Asian populations might express these genomic variants less than European and American populations. Our current finding suggested that these susceptibility genes and associated genetic variants might play a critical role in chickenpox progression based on host genetics with clinical implications.

8. Discussion

Chickenpox is a virus-indused disease that infects humans and is transmissible via airborne or direct contact [11]. In this study, we examined the influence of *HLA-S*, *HCG4P5*, and *ABHD16A* on the tissue expression of chickenpox. Chickenpox symptoms include fever, headache, backache, chills, nausea, and vomiting [3] and accompanied by a rash on the entire body's skin surface [4]. The gene responsible for chickenpox, *HLA-S*, has been reported as a potential factor in herpes zoster disease [12], whose primary cause is VZV [13]. It is important to note that *HLA* belongs to the human leukocyte antigen (HLA) family, which produces a protein that plays a critical role in the immune system. *HLA-S* is part of a family of genes called *HLA* complex. The previous study reported that the *HLA* complexes assist the immune system in distinguishing between proteins made by the body and those made by foreign invaders such as viruses and bacteria [14]. It is known that the previous study reported the variants of *HLA-A*33* and *HLA-B*44* were at a strongly higher risk of developing Postherpetic neuralgia (PHN) in patients suffering from VZV infectious disease [13]. Other findings supported the study by revealing that the *HLA-A*02* in patients with atherosclerosis is associated with VZV seropositivity [15].

According to HaploReg version 4.1 bioinformatic database revealed that [https://pubs.broadinstitute.org/mammals/haploreg/haploreg.php], these three variants (rs9266089, rs10947050, and rs79501286) were involved in the changing chromatin status of primary T cells from

Table 2
Variants associated with chickenpox were expressed in the skin tissue.

SNP Id	Genecode Id ENSG00000	Gene Symbol	*p*-value	NES	Tissue	Expression

Fig. 4. Distribution of allele frequencies of the three variants (rs9266089, rs10947050, rs79501286) affecting *HLA-S, HCG4P5*, and *ABHD16A* among different populations across continents. This figure was created with BioRender.com under agreement number "CX24TS7TWB ".

peripheral blood, which plays a central role in the "primary immune response" of cell-mediated immunity. Furthermore, *ABHD16A* is a protein with a hydrolase/domain that has been linked to familial metabolic disorders [16]. We noted the important roles played by the *ABHD16A,* human *ABHD16A* is also known as human leukocyte antigen B (*HLA-B*). Another observation of interest for gene *ABHD16A* supported that the gene could play an important role and function in immune regulation processes [17]. Moreover, *ABHD16A* is associated with immunoregulation [18], kawasaki disease, and coronary artery aneurysms [19]. Another gene, such as *HCG4P5* is also known as *HLA* complex group 4 pseudogene 5 [ENSG00000227766] *HLA* class I and functions for interferon signaling [20,21]. It is well known that Interferon plays a critical role in the human immune response [2]. Human genomic expression levels and patterns in different tissues might be critical for evaluating the susceptibility, symptoms, and outcome of disease, including for chickenpox infectious disease. We sincerely expect the results could be of immense essential in understanding the genetic basis of chickenpox infectious disease. Therefore, we strongly recommend that future research investigate these variants' functions, interactions, and mechanisms in the human body.

Multiple clinical characteristics and susceptibility loci were associated with VZV infection. *HLA* is located on chromosome 6 and is associated with VZV-caused herpes zoster [10]. *ABHD16A* is a member of the alpha-beta hydrolase domain-containing (*ABHD*) family of serine hydrolase metabolism, also referred to as leukocyte antigen-B- (*HLA-B*)-associated transcript 5 (*HLA-B*-associated transcript 5, *BAT5*), which is associated with familial hereditary metabolic disease [16]. We examined chickenpox-associated genetic variants using publicly accessible databases, such as the GWAS catalog [22], Haploreg version 4.1 [23], GTEx portal [24], and Ensembl [25]. Multiple studies have utilized these integration techniques to identify the *TMPRSS2* gene [26], the *ACE2* gene for COVID-19 [26], and a variant for Sjogren syndrome [27]. *HLA-S*, *HCG4P5*, and *ABHD16A* influence the occurrence of chickenpox, which causes fever, headache, backache, chills, nausea, vomiting, and a rash throughout the skin [3,4]. Currently, it is interesting to evaluate and use the variants for a variety of purposes. The variants are not only can guide the susceptibility of the diseases but also can be utilized to drive drug discovery [28–31].

In our study, we highlighted that the variants of rs9266089, rs10947050, and rs79501286 may affect the expression of *HLA-S, HCG4P5,* and *ABHD16A***,** respectively. Based on our study, the AA genotype of rs9266089 had a higher *HLA-S* expression in the skin tissue than the GA (intermediate) and GG (lowest) genotypes (Table 3 and Fig. 3). The A allele frequency of SNP rs9266089 was 2% in Asians compared to Europeans, Americans, and Africans (Fig. 4). At rs10947050, the TT genotype had a higher *HCG4P5* skin expression than the heterozygous CT (intermediate) and homozygous CC (lowest) among European, American, and African populations. African populations had the lowest frequency of the T allele of SNP rs10947050, at 13%, compared to European, American, and Asian populations (Fig. 4). While the AA genotype at rs79501286 in *ABHD16A* had a higher expression in the skin than the heterozygous GA genotype (middle expression) and homozygous GG genotype (lowest expression) (Table 3 and Fig. 3), which were related to chickenpox illness susceptibility. The A allele frequency of SNP rs79501286 showed the lowest yield in Asian and African populations at 1% compared to European and American populations (Fig. 4)~~.~~ Asian individuals had the lowest allele frequencies in the skin for the variations (rs9266089, rs10947050, and rs79501286) related to chickenpox illness compared to European, American, and African groups. Consequently, it can be suggested that European, American, and African populations may have more individuals with the trend of elevated expression of *HLA-S, HCG4P5*, and *ABHD16A* compared to Asians, which may contribute to an increase in the susceptibility to chickenpox disease.

Overall, the allele frequencies of the variants (rs9266089, rs10947050, and rs79501286) that are associated with chickenpox disease showed the lowest allele frequencies in the Asian population. Thus, it can be assumed that European, American, and African populations may have more individuals with increased expression of *HLA-S, HCG4P5*, and *ABHD16A* compared to Asians, which may contribute to an increase in susceptibility to chickenpox disease. This study identified gene variants *in silico*, which must be validated in the clinical implementation of the varicella-zoster virus. However, we believe that meta-analysis based approach is essential to sharpen our prediction as a more comprehensive range of genetic variant data associated with chickenpox becomes available. In addition, further research is needed to validate our findings using functional studies. The validation aims to ascertain whether these variants have a critical role and could harbor a clinically actionable variant for the varicella-zoster virus.

9. Conclusion

Our study emphasizes the investigation of genetic variations influencing chickenpox that revealed the highest expression of *HLA-S*, *HCG4P5*, and *ABHD16A* in the skin tissue. These genes affected the chickenpox risk in individuals and populations. We discovered that the variants rs9266089, rs10947050, and rs79501286 affected *HLA-S*, *HCG4P5*, and *ABHD16A* expression, respectively. Allele frequency is crucial when predicting chickenpox illness susceptibility on multiple continents. Future avenues of research would aim to verify the impact of these variants and their clinical actionability in the diagnosis and management of chickenpox patients.

Author contribution

L.M.Irham and W. Adikusuma conceived and designed the study. L.M.Irham and W. Adikusuma performed the computational analysis. L.M. Irham wrote the manuscript. L.M.Irham provided the funding. A R Afief., A.N Puspitaningrum., Lolita., M.A.Sarasmita and H Dania.,S Khairi, Gina N Djalilah, B Djaka Purwanto and Rocky Cheung revised the manuscript. All authors have read and approved the manuscript and have made significant contributions to this study.

The genetics of depression: successful genome-wide association studies introduce new challenges

Johan Ormel[1], Catharina A. Hartman[1] and Harold Snieder[1]

Abstract

The recent successful genome-wide association studies (GWASs) for depression have yielded more than 80 replicated loci and brought back the excitement that had evaporated during the years of negative GWAS findings. The identified loci provide anchors to explore their relevance for depression, but this comes with new challenges. Using the watershed model of genotype–phenotype relationships as a conceptual aid and recent genetic findings on other complex phenotypes, we discuss why it took so long and identify seven future challenges. The biggest challenge involves the identification of causal mechanisms since GWAS associations merely flag genomic regions without a direct link to underlying biological function. Furthermore, the genetic association with the index phenotype may also be part of a more extensive causal pathway (e.g., from variant to comorbid condition) or be due to indirect influences via intermediate traits located in the causal pathways to the final outcome. This challenge is highly relevant for depression because even its narrow definition of major depressive disorder captures a heterogeneous set of phenotypes which are often measured by even more broadly defined operational definitions consisting of a few questions (minimal phenotyping). Here, Mendelian randomization and future discovery of additional genetic variants for depression and related phenotypes will be of great help. In addition, reduction of phenotypic heterogeneity may also be worthwhile. Other challenges include detecting rare variants, determining the genetic architecture of depression, closing the "heritability gap", and realizing the potential for personalized treatment. Along the way, we identify pertinent open questions that, when addressed, will advance the field.

Introduction

Major depressive disorder (MDD, henceforth: depression) is a common mental disorder. In most Western countries, MDD has a 1-year prevalence of ~5%[1,2] and a lifetime prevalence of ~15%[3]. Depression is in the top three of the leading causes of years lived with disability and a significant contributor to premature mortality due to suicide[4,5]. Twin-based heritability estimates typically fluctuate around 35%. Candidate gene studies have not implicated replicable gene variants[6] and—until very recently—genome-wide association studies (GWASs) had neither[7,8].

This long drought without much progress in understanding the genetics of depression has recently ended. The CONVERGE consortium focused on a homogeneous subtype of carefully phenotyped recurrent, severe depression, and identified two genetic loci exceeding genome-wide significance levels[9]. Shortly thereafter, GWASs that used the alternative strategy of increasing sample size while using a more lenient, easy to measure, depression phenotype (i.e., "minimal" phenotyping) have identified additional genetic variants[10–12], culminating in the most recent successes of GWASs conducted in the UK Biobank ($n = 322{,}580$; 16 independent loci associated with broad depression phenotypes)[13], the PGC MDD working group (130,664 MDD cases and 330,470 controls; 44 independent loci)[14], and the Howard et al. meta-meta-

analysis of data on 807,553 individuals (246,363 cases and 561,190 controls) from the three largest GWASs of depression using minimal phenotyping[15]. Howard and colleagues identified 102 independent variants of which 87 replicated in an independent sample. Finally, GWAS findings on multiple psychiatric phenotypes were leveraged to identify eight novel independently replicated depression loci[16].

With this successful harvest of GWAS loci for depression, the next wave of challenges has come to the fore. Using the watershed model of genotype–phenotype relationships as a conceptual aid and recent genetic insights on other complex traits such as height, we discuss first why it took so long, followed by seven challenges that need further work to advance the field. The biggest challenge is probably the identification of genetic variants that are causally involved in MDD. These challenges are not unique to depression but apply in varying degrees to highly polygenic conditions in general. Nonetheless, we focus this paper on depression for two reasons: (1) Depression is an interesting mental disorder because of its high prevalence and relatively small twin-based heritability, and (2) It affords a clear focus and obviates the need to include information about many other polygenic conditions. Depression contrasts strongly with human height, a complex trait like depression, which is—unlike depression—highly heritable and measured with less error. Below, we often use height as a contrasting complex trait. Gene finding studies for height have shown much more rapid returns than for depression and may give insight into what we might expect for depression in the near future with much larger sample sizes compensating for its lower heritability and larger measurement error.

Why did it take so long?

Keller and Cannon's watershed analogy of the genotype–phenotype relationship is helpful in explaining why the identification of genetic loci for depression has been extremely difficult (Fig. 1)[17]. Much like the numerous streams of the Amazonian watershed that merge and eventually empty into the Atlantic Ocean, sets of genetic variants influence upstream micro-biological processes (narrowly defined mechanisms; e.g., dopamine transmission) that influence intermediate "downstream" meso-biological processes (e.g., working memory, facial emotion recognition) that in turn affect macro-biological processes (e.g., stress sensitivity, affect regulation), which contribute to the overall fitness of the individual. Gene variants that are directly involved in an upstream process not only affect that upstream process, but indirectly also many processes and traits downstream. If enough noise is present in particular upstream processes, specific behavioral syndromes may arise, such as symptoms of mental disorder. The more upstream (specific, narrow) the (intermediate) phenotype is, the closer its relationship to the genetic variants that affect it, thereby increasing the probability that the associated genetic variants are truly involved in the production of the phenotype.

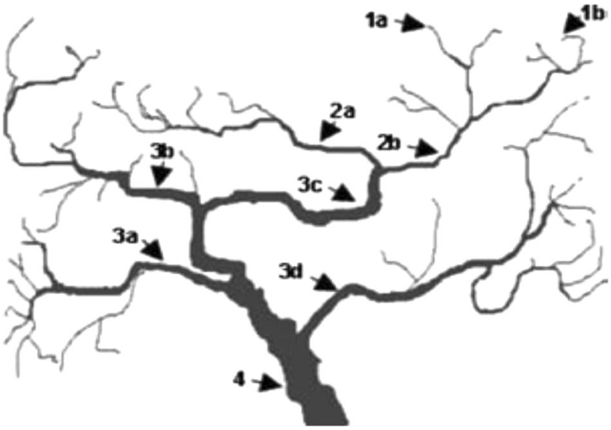

Fig. 1 The watershed model of the pathways connecting upstream genetic variants to downstream depression. Mutations at specific loci (1**a**, 1**b**) disrupt narrowly defined mechanisms such as transmission of dopamine in the prefrontal cortex (2**b**). This and other narrowly defined mechanisms contribute noise to more broadly defined mechanisms, such as working memory, facial emotion recognition (3**c**). The latter mechanisms in conjunction with several other mechanisms (3**a**, 3**b**, 3**d**) affect observable phenotypes, such as stress sensitivity, affect regulation. All tributaries eventually flow into fitness (4). Adapted from Keller & Miller, 2006[17]

Depression is a rather downstream phenotype, almost at the level of fitness (Fig. 1). This feature may explain why it took so long for GWASs of depression to become successful. First, as illustrated by the watershed model of genotype–phenotype relationships, multiple tributaries may lead to the same phenotypic outcome (so-called equifinality), with the implication that depression is etiologically heterogeneous, consistent with current insights. This hampers attempts to identify the genetic loci for depression since all individuals with depression are lumped together, which dilutes the explained variance of a particular variant[18].

Second, depression is not only etiologically but also phenotypically heterogeneous. Approximately 1500 DSM-IV symptom combinations can fulfill the diagnostic criteria[19]. Two patients diagnosed with depression may have very few symptoms in common. In addition, phenotypic heterogeneity will be enhanced by co-occurring psychiatric problems. Two patients having similar depression symptoms may have different comorbid conditions (e.g., anxiety disorder versus substance use disorder). Again, this will dilute the effects of a particular variant.

Third, the upstream processes involved in depression are hardly known, with problematic consequences for the use of "endophenotypes". To date, the endophenotype approach in depression has not been able to live up to its promises. Many depression-related endophenotypes proposed in the past were based on stress research and neuroimaging, and thus still at relatively low levels in the watershed model. Such endophenotypes tend to be as genetically complex as their outcome phenotypes[20].

Fourth, phenotypes downstream in the watershed are more likely to be "constructs" rather than biological "entities", which introduces measurement error. Depression, whether measured by inventories, (semi-)structured interviews, or clinical assessments, is subjective and based on reported and observed affect, cognition, and behavior. Human height, by comparison, is a much simpler phenotype that can be obtained objectively and reliably. Moreover, measurement of depression is complicated by its mixed course, ranging from a single lifetime episode to chronic-recurrent. Even during an episode symptoms often fluctuate. This complicates measurement since retrieving "the most severe episode" from memory implies retrospective assessment with all its reliability problems. For example, it has been shown that SNP heritability is considerably higher for emotional problems when focusing on the stable variance over time compared to single measures per time point, which further illustrates the relative advantage of height, which remains constant over the adult life course, over depression as a phenotype for genetic studies.

Challenges pertinent to the interpretation and utility of detected genetic variants

With the recent GWAS successes of identifying more than 80 replicated loci, the next wave of challenges for the genetic study of depression come to the fore.

Challenge 1. Prioritizing likely causal genes for functional follow up

An important characteristic of GWASs is that the identified variants merely flag genomic regions without necessarily providing a direct link to the underlying biological mechanisms[21]. In addition, the identified variant may not be (directly) causal to the phenotype of interest but to other phenotypes that are strongly associated with the phenotype of interest, including comorbid conditions and intermediate traits in the causal pathway leading to the final outcome. Furthermore, effect sizes of individual genetic variants are typically very small (although this does not rule out that effect sizes on currently unknown micro-biological phenotypes higher in the watershed can be large)[22]. All in all, the selection of the most promising signals and the discovery of their functional consequences represent a major challenge. Given the costs and difficulties of conducting functional studies, prioritization of likely causal genes is very important. For the approximately 80+ depression loci this is a formidable task. To date, bioinformatics analyses have been the main strategy.

Fine-mapping of identified loci is typically used as a first step to limit the "credible set of SNPs" that likely include the causal variant(s) responsible for the observed GWAS signals. Transethnic differences in linkage disequilibrium can be used to improve its resolution[23]. However, with the exception of the CONVERGE study of recurrently depressed Han Chinese women, depression GWASs have been limited to individuals of European ancestry. Therefore, more GWASs in other ethnic groups are needed to aid fine mapping efforts. Further bioinformatic post-GWAS follow up analyses leverage the fact that there are only two biological mechanisms that can explain true SNP–phenotype associations: (1) the SNP may alter the amino acid coding (i.e., a nonsynonymous SNP) changing the protein structure and potentially its function, alternatively; (2) it may exert its phenotypic effect through influencing the expression of the gene. Therefore, bioinformatic post-GWAS pipelines will check whether GWAS signals will be in high linkage disequilibrium with nonsynonymous SNPs within nearby genes and use publicly available expression Quantitative Trait Loci (eQTL) resources from relevant tissues such as the brain (GTEx, Braineac) or whole blood to check which SNPs in the identified loci are also associated with gene expression[24].

Recent tools integrate evidence from GWAS with eQTL data within a Mendelian randomization framework allowing assignment of likely causality of genes within loci[25–27]. The Mendelian randomization approach is based on the fact that the DNA sequence is fixed, which implies that causation can only flow in one direction, allowing the use of genetic markers as instrumental variables. With the advent of GWAS and the recent explosion in variant discovery, this simple idea has been applied to great effect[28]. It has been used in particular to examine the causality of correlated phenotypes and the origins of genetic correlations (see also Challenge 4). But it can also be used to explore the causal role of genes within identified genetic loci for the phenotype of interest[25].

Mendelian randomization in its most basic form is summarized in Fig. 2 where the causal relationship between an exposure (e.g., obesity) and an outcome (e.g., depression) is investigated (association 1 in Fig. 2) using genetic variants known for influencing the exposure (obesity) (association 2) as an instrumental variable, by estimating the association between the genetic variants and the outcome (depression) (association 3)[27].

Mendelian randomization has three important assumptions (see Fig. 3). First, the genetic variants should have a robust and strong relationship with the exposure (a). Second, the variants must not be associated with factors that confound the association between exposure and outcome (b). Third, the genetic markers for the exposure only influence the outcome through their effect on the exposure and not through any other pathway (c). Although the latter two assumptions are hard to prove, many Mendelian randomization sensitivity analyses have recently been developed that are less reliant on these assumptions[29].

Further bioinformatic analyses may explore whether genes within the GWAS loci are preferentially expressed in certain tissues or enriched in certain networks and pathways, and whether these genes are targets of existing (e.g., psychiatric) medications[22,30]. Ultimately, unequivocal evidence of underlying mechanisms will have to come from functional studies such as the one showing a role in synapse pruning for the *C4A* gene in schizophrenia[31]. Developing and increasing throughput of either cell-based or animal model assays to investigate the many GWAS loci for function will be one of the main challenges for the immediate future.

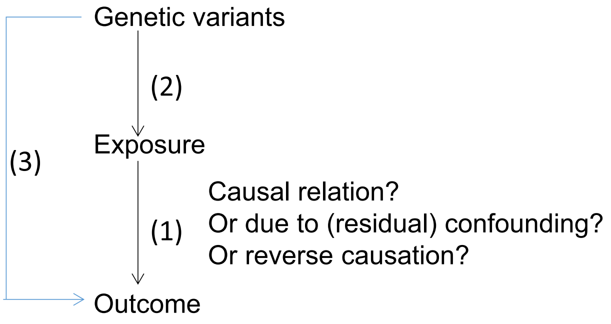

Fig. 2 Framework of a Mendelian randomization study in its most basic form. Adapted from Verduijn, 2010[27]

Challenge 2. Finding rare and more common variants

Given the relationship between sample size and the number of detected loci, it is to be expected that larger sample sizes will identify additional loci. These will include common variants with (even) small(er) effects and probably rare variants of moderate-to-large effect although their role in depression is currently unknown[32]. The brief history of GWASs of, for example, schizophrenia, supports the expectation that with larger sample sizes rare variants can be discovered. In general, the contribution of rare variations of strong effect tends to be larger for early-onset, highly heritable, severe (e.g., neurodevelopmental disorders, including schizophrenia) disorders and lesser for disorders that are less heritable, less severe and with a later onset, such as depression[30]. But that does not exclude a role for rare variants in depression.

The support that rare variants may play a role in depression also comes from large GWASs of complex traits outside psychiatry, most notably human height[33,34]. Some rare variants (minor allele frequencies [MAFs] 0.8–2.1%) had large effects, implicating a 2 cm difference in height. The explained variance of genetic variants is a simple function of both effect size and MAF. As such, despite their much larger effect size, the rare height-associated genetic variants each explain, on average, similar amounts of variation at the population level as common variants. The much lower effect size of common variants is “compensated” by their much higher frequency.

Fortunately, costly whole genome or exome sequencing may not be necessary to find rare variants, as large GWAS sample sizes of a million individuals or more, imputed to very large sequenced reference samples will offer sufficient resolution and power in the low frequency range and

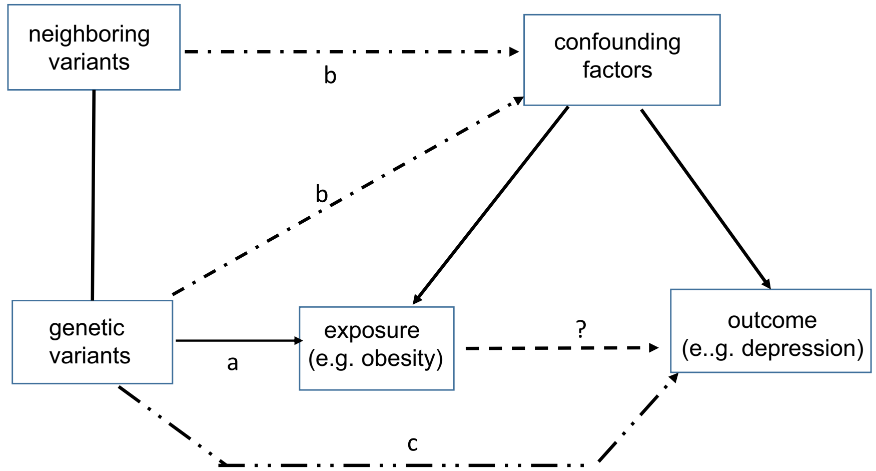

Fig. 3 Assumptions made in Mendelian randomization: (**a**) presence of a robust association between genetic variants and exposure (here depression), (**b**) absence of (direct/indirect) association between generic variant and confounding factors, and (**c**) absence of other pathways between genetic variants and outcome. Adapted from Verduijn, 2010[27]

are now increasingly feasible[35,36]. Furthermore, the strong phenotypic and genetic correlation between depression and other mental disorders may be leveraged to improve power and identify both additional common and novel rare variants for depression[16].

Challenge 3. Establishing the genetic architecture of depression

Initially, GWASs of complex traits operated from the simple common disease–common variant (CDCV) model, positing that a moderate number (<100) of gene variants of intermediate frequency (MAF > 5%) with small-to-moderate effect (OR > 1.5) account for the heritability of the trait. The results of recent GWAS studies of complex traits, including height, have shown this CDCV model to be wrong for most types of complex traits[37–39]. Four alternative models of genetic architecture have been proposed: (i) the *infinitesimal* model assuming that heritability is due to a large number (»100) of small-effect common variants, (ii) the *rare allele* model, assuming that heritability is due to a large number of rare variants with relatively large-effects (including copy number variants), (iii) the *broad-sense heritability* model, assuming that in addition to additive effects of common variants, heritability is due to rare variants, non-additive GxG (dominance, epistasis) and GxE interactions as well as epigenetic effects, and (iv) the *omnigenic* model hypothesizing that the genetic architecture of complex traits is characterized by very large numbers of peripheral, more general genes and a limited number of "core" genes, assumed to be more disease specific[37,40].

Apart from the yet to be detected occasional rare variants, the infinitesimal model may provide a good approximation for a highly polygenic disorder like depression. Regarding non-additive GxG and GxE interactions, decisive evidence is lacking as to date GWASs have not been designed and powered to detect GxG and GxE interactions, neither for depression, nor for other mental disorders or height. Recent studies were unable to show a sizable influence of dominance for a wide range of complex traits[41]. Previous attempts to study GxE on the basis of single candidate genes[42,43] are now being replaced by the use of polygenic risk scores (e.g., refs. [44,45]). which may offer more promise for detection of GxE interaction, although the polygenic risk scores will only provide a general measure of genetic susceptibility for depression that does not directly indicate underlying mechanisms. Moreover, the use of polygenic risk scores neglect the possibility that the impact of GxE interaction is not consistent across different genes or pathways; some genetic pathways may show GxE interaction but others may not or in the reverse direction. Nonetheless, it is likely that these interaction studies will eventually be successful given, for example, "indirect" evidence of substantial GxE interactions between personality traits and environmental exposures[46,47]. Regarding the omnigenic model, Wray and colleagues have recently argued that, although intuitively appealing, there is insufficient empirical evidence for the existence of its hypothesized core genes[18].

Irrespective of the correct model for the genetic architecture, it must reserve an honorable seat for environmental influences. In addition to the aforementioned interactions, two epidemiological observations support a substantial environmental component in the etiology of depression: Although depression can be found everywhere, substantial national and regional variations in prevalence exist[3,48]. Because of the ultimately subjective nature of the measurement process, these prevalence differences are hard to interpret. Furthermore, strong effects on risk for depression have been documented for long-term difficulties (e.g., taking care of a dementing partner, persistent unemployment, victim of chronic bullying) which in addition moderate the depression risk of stressful life events (e.g., acute illness of child, let down by friend)[46,49–51]. The latter short-term factors are typically thought to play a role in the timing of depression onsets pushing susceptible individuals across the diagnostic threshold. Although such environmental effects partly reflect depression's genetic background (i.e., gene–environment correlation); they are nonetheless likely to have an extra, additive, contribution to, as well as interaction with, genetic risk in explaining the depression phenotype.

Challenge 4. Genetic pleiotropy and unraveling causal relationships with other traits

Pleiotropy is the phenomenon whereby a genetic variant influences two or more phenotypes[52]. In line with high comorbidity across mental disorders, GWAS findings also indicate substantial genetic overlap, although the extent thereof was perhaps unexpected[53]. SNP-based genetic correlations (r_g) between depression and other mental disorders are substantial[14]. Pleiotropy is not specific to psychiatry and has also been shown between depression and somatic conditions[14,54,55].

Part of the genetic correlations may derive from symptom/diagnostic overlap, comorbidity or can even be an artefact of diagnostic misclassification. It is useful to make a distinction between heterogeneity due to different symptom patterns that all meet MDD's diagnostic criteria and heterogeneity due to comorbidity with other mental disorders, a common phenomenon. Genetic correlations may also reflect a common cause. For example, virtually all mental disorders involve sensitivity to stressful situations which is why individual differences in appraisal of and coping with stressful experiences have an impact on the severity of their manifestation. This commonality implies that genetic variants that influence appraisal and coping may turn up in GWASs of these mental disorders, although they are at best causally involved in a generic way, not strictly part of the specific disorder's pathophysiology. In the watershed model, these shared appraisal-coping or executive functioning related variants are probably located relatively upstream, with many confluences downstream. The higher hierarchical position makes it "easier" to be involved in multiple phenotypes than variants more downstream.

A unique feature of genetic as opposed to classic epidemiological associations that aids in unraveling causality is that confounders (or third variables) that influence both genetic markers and outcome phenotypes do not exist (DNA is fixed). Mendelian randomization can thus also be used to disentangle the causes of correlated traits using genetic markers to distinguish between alternative causal explanations such as reverse causation and shared causes[56]. One important requirement for effective Mendelian randomization is the availability of a sufficient number of genetic markers associated with the exposure as their combined effect determine the strength of the instrumental variable. This means that distinguishing causality between depression and associated traits using Mendelian randomization has only recently become possible. The continued discovery of additional genetic variants for depression will be important to improve their strength as an instrumental variable and hence the power of Mendelian randomization analyses in order to distinguish between alternative causal pathways, thereby providing fresh clues to old questions.

Challenge 5. Closing the "heritability gap"

Genetic variants detected by GWAS typically explain only a fraction of the total family- or twin-based heritability. This has become known as the missing heritability problem or heritability gap[41,57]. Recently introduced methodology now also allows calculation of the SNP- or chip-based heritability (h^2_{SNP}), which is the proportion of phenotypic variance jointly accounted for by all variants on a standard GWAS chip. h^2_{SNP} provides an upper bound estimate of the genetic effects that could be detected by a (well-powered) GWAS[58]. The remainder is likely due to rarer and structural variants that have until recently not been captured by regular GWAS arrays[35]. The latest PGC depression GWAS estimates this h^2_{SNP} at ~9%, which is only around a quarter of the heritability based on twin and family studies of ~35%. However, measurement error and heterogeneity in phenotype definition between the different PGC cohorts may explain part of the difference in heritability as the CONVERGE study found a h^2_{SNP} between 20 and 29% within their cohort of carefully assessed women with early-onset recurrent depression.

Another part of the heritability gap may be attributed to potentially inflated twin heritability estimates caused by gene by common (C) (or shared) environment (GxC) interactions[45]. That is, genetic effects depend on environmental factors shared by twins that grow up in the same family but not by unrelated individuals in the GWAS samples. The statistical models used in twin studies to estimate twin-based heritability fully attribute the joint effect (GxC) to the genetic component, thus inflating heritability estimates and reducing the contribution of shared environment. The GxC explanation "solves" not only (part of) the heritability gap but the shared environment paradox as well. This paradox refers to the apparent inconsistency that, in contrast to epidemiological studies, the statistical models used in twin studies typically find hardly any shared-environmental variance while many (distal) environmental risk factors are shared by twins in the same family, e.g., poverty, family instability, child neglect, neighborhood stressors, minority status, SES[59]. As pointed out by Uher and Zwicker[45], this paradox disappears if we realize that the impact of these shared-environmental factors depends on characteristics shared to a larger extent by monozygotic than dizygotic twins, i.e., genetic variants.

The difference between heritability explained by GWAS identified variants and the h^2_{SNP} has also been more aptly termed "hidden" heritability as future larger GWASs are expected to detect additional signals still hidden in the noise. Furthermore, new generations of denser and better-imputed GWAS arrays are expected to capture more rare and structural variants, which will increase the h^2_{SNP} and decrease its gap with the total (potentially inflated) (family and twin-based) heritability[35,57].

Challenge 6. Reducing the phenotypic heterogeneity

A major challenge is the identification of genetic variants that are causally involved in MDD and this is aggravated by the use of minimal phenotyping (based on a few symptoms), which, as recently shown, may have yielded cases unrepresentative of MDD that are enriched by people "with non-specific sub-clinical depressive symptoms and depression secondary to a comorbid disease"[60].

Traditionally, endophenotypes of depression have been used in the hope that this would shorten the distance between genes and phenotype, and consequently reduce genetic heterogeneity. To date, the expectations have not come true as the used endophenotypes were genetically not less complex. However, the recently identified genetic signals may provide new insights into underlying pathophysiological pathways and networks providing clues on more suitable less complex endophenotypes (micro-biological phenotypes) that are at higher levels in the watershed model and thus closer to the genes. Constructs assessed through task performance such as reward sensitivity and attentional biases may have potential utility as endophenotypes if they are associated with genetic signals. Given their transdiagnostic relevance, they may also account for other disorders in which these mechanisms are active as well.

Some argue that another way forward lies in the reduction of phenotypic heterogeneity, by targeting a specific subtype such as early-onset recurrent melancholia or a specific symptom cluster[9]. Others believe that a broader phenotype approach will provide a more tractable target for genetic studies, as this identifies more signals[11]. Findings of the CONVERGE consortium based on a sample size that was much smaller than the other recent depression GWASs suggests that in-depth phenotyping may pay off[9]. In addition to high-quality measurement of depression, this study focused on recurrent severe depression which may be genetically more homogeneous. However, CONVERGE differed in additional aspects from the other MDD GWASs, including the Chinese sample, the focus on women, and analytical approach. We cannot rule out that these differences contributed to CONVERGE's success.

The recent GWASs successes with broad phenotypes of depression and neuroticism[61] seem to support the broad trawl approach[13]. But note that phenotype broadness is subject to more noise because the likelihood that identified loci are not involved in the physiology of the phenotype of interest increases with broadness (see Challenge 4).

In contrast to broader milder depressive states, other clinically recognizable "subtypes" of depression including early-onset recurrent depression and the more severe subtypes of melancholic, bipolar, and psychotic depression may also be less heterogeneous[62–64]. It is also important to keep in mind that even highly homogeneous subtypes defined by behavioral symptoms are still placed low in the watershed model and remain multifactorial, with multiple underlying etiological pathways although they may be less genetically heterogeneous than all "depressions" lumped together.

Novel approaches improving the phenotype definition of depression may be needed. We outline two complementary approaches below that make use of depression measured at the most narrow level of individual symptoms.

Bottom-up: individual symptoms of depression as a starting point

Symptom-specific GWASs to examine their genetic background may be an interesting next step. Previous depression GWASs have used composite scores or diagnostic case-control designs. Based on data from the UK Biobank, Nagel and colleagues[65] showed that the composite score of neuroticism, an important personality trait that partially overlaps with depression[66], directs the focus to genetic variants that affect the majority of aggregated items, i.e., "global variants". The genetic signal of "local" variants, affecting only one or a few of the aggregated items, was severely diluted[65]. Given its multidimensional and heterogeneous nature, it is plausible that symptom-specific GWASs of depression will yield similar findings. Some initial evidence comes from a relatively small sample showing that h^2_{SNP} of four depression symptom components (appetite, depressed mood and anhedonia, insomnia, and anxiety) was different, suggesting the possible merit of more narrowly defined phenotypes[67].

Top-down: use hierarchical dimensional models

Hierarchical dimensional models such as the Hierarchical Taxonomy of Psychopathology (HiTOP)[68] show how psychopathology dimensions can be arranged in a hierarchy, ranging from very broad "spectrum level" dimensions (e.g., distress, thought disorder, disinhibited externalizing, etc.), to more specific clusters of symptoms. For instance, the distress spectrum, one of the five internalizing spectra consists of the lower clusters (subdimensions) of irritability, anhedonia, numbing, physical panic, suicidality, dysphoria, retardation, lassitude, appetite loss, insomnia, and generalized anxiety[69]. These models hypothesize a hierarchy linking spectrum level dimensions with highly pleiotropic variants which subsume lower order symptom clusters with less pleiotropic variant clusters. This phenotypic ordering from narrow to broad may help in the interpretation of genetic findings.

Challenge 7. Personalized treatment

An important issue is the utility of identified variants for individualized treatment of depression. Three applications may be genomic (polygenic) risk prediction, genome editing, and the identification of novel "druggable" targets, respectively. GWAS results can be used for genomic risk prediction. Increased risk could prompt more intensive surveillance or even prophylactic treatments unrelated to a specific causal mechanism (cf. preventive mastectomy in case of high genetic breast cancer risk). The widespread pleiotropy among mental disorder phenotypes (genetic correlations) can be used to improve genomic risk prediction, so that this might benefit personalized medicine[70]. However, genetic risk-driven prophylactic treatment is not realistic yet, given the low effect size of SNP-based genetic predictors[70].

Genome-editing technology such as CRISPR/Cas9 may make it possible to change or disable genes in living cells in a precise, cheap, and fast way by cutting, replacing, or adding pieces from the DNA[71,72]. However, it is highly doubtful whether this will ever have relevance for "fixing" depression-associated genetic variants due to their small effect sizes, unknown individual relevance (from population to individual), causal relevance (too upstream), and unwanted "side" effects of genome-editing (genetic pleiotropy).

With regard to pharmacotherapy, virtually all currently used drugs in psychiatry have their origins in chance findings in the previous century, while rational approaches to develop new pharmacological treatments have mostly not paid off. The recent findings from the PGC depression GWAS indicated that lead SNPs in some loci were within genes known to play a role in neuronal development, synaptic function, transmembrane adhesion complexes, and/or regulation of gene expression in brain. In addition, genes that are targets of antidepressant medications were strongly enriched for depression-associated signals, which may indicate pharmacotherapeutic relevance[73]. In addition, some identified loci were associated with clinical features of depression including early-onset, recurrence, and severity, and implicated prefrontal and anterior cingulate cortex in the pathophysiology of depression (brain regions showing MRI anatomical and functional differences between MDD cases and controls). Thus, current genomic findings may have substantial potential for the development of new depression medications. The future will tell.

However, the complex genetic nature of depression raises the question for whom drugs developed on the basis of GWAS findings will work. For a highly complex trait-like depression, each individual probably carries a unique combination of protective and risk alleles (see ref. [18] for an illustration). The more polygenic a trait, the more combinations of these sets of alleles are possible, implying that each individual is likely to have a different combination, including affected individuals whose symptom levels have crossed the diagnostic threshold. This explains why most mental disorders are highly heritable but only weakly inheritable[22]. Due to genetic recombination, the probability that a child will inherit a mix of alleles from an affected parent resulting in a genetic risk sufficiently high to also pass the diagnostic threshold remains fairly small. Thus, effect sizes derived from GWASs of a genetic variant with depression should be interpreted in the context of an averaged background; in individual carriers the contribution of a certain variant may be much larger. A particular drug can be effective only in the subgroup of individuals that share the genetic variant and pathway targeted by the drug. The effectiveness of a drug in the individual case thus depends on the number of possible combinations in which the particular variant is a necessary component to become depressogenic. Ultimately, precision medicine for highly polygenic disorders like depression may depend on successfully matching these unique individual genomic profiles to drug treatments[18].

Conclusion

Clearly, the excitement for investigating the genetic background of depression has returned. Prospects to unravel the pathogenesis and etiology of depression and rationally develop pharmacotherapies are better than ever. Now that depression-associated genetic variants have been found, the next wave of challenges has taken center stage. It is likely that larger samples will identify additional common variants and the first batch of rare variants, which will reveal the genetic architecture of depression, its subtypes and broader phenotypes. It is also likely that taking common (C) (or shared) environment (GxC) interactions into account will contribute to unearthing part of the missing heritability[45]. The GxC explanation not only bridges (part of) the heritability gap but also may explain the shared environment paradox.

The largest challenges will be to identify the causal variants of depression itself and to determine which variants merely correlate with the depression phenotype because they are causally involved in its determinants. In addition to bioinformatics, Mendelian randomization may help to resolve this causal web and will become increasingly effective with the identification of additional genetic variants of depression and related phenotypes. To date, Mendelian randomization has almost exclusively been used to aid in the interpretation of genetic correlations between correlated phenotypes, but it may also assist in distinguishing causal from pleiotropic depression variants. Another approach to clarify the causal status of genetic variants might be comparing markers associated with narrowly (e.g., early-onset recurrent melancholic depression) versus broadly defined depression phenotypes. Likewise, comparing the variants associated with different levels of the "depression hierarchy" (symptoms, clusters of symptoms, internalizing dimensions, general psychopathology factor) might be informative. Finally, the fact that highly polygenic traits are only weakly inheritable despite substantial heritability[22] could explain the seeming paradox that antidepressants may benefit individual patients enormously despite their modest average efficacy on a group level compared to pill-placebo[74].

Conflict of interest

The authors declare that they have no conflict of interest.

The Novel *ASIC2* Locus Is Associated with Severe Gingival Inflammation

S. Zhang[1,2], K. Divaris[3,4], K. Moss[2], N. Yu[2], S. Barros[1,2], J. Marchesan[1,2], T. Morelli[1], C. Agler[5], S.J. Kim[2], D. Wu[1], K.E. North[4,6], J. Beck[2,7], and S. Offenbacher[1,2]

Abstract: *An increasing body of evidence suggests a significant genetic regulation of inflammatory response mechanisms; however, little is known regarding the genetic determinants of severe gingival inflammation (GI). We conducted a genome-wide association study of severe GI among 4,077 European American adults, participants in the Dental Atherosclerosis Risk in Communities cohort. The severe GI trait was defined dichotomously with the 90th percentile of gingival index ≥2 extent score. Genotyping was performed with the Affymetrix 6.0 array platform, and an imputed set of 2.5 million markers, based on HapMap Phase II CEU build 36, was interrogated. Genetic models were based on logistic regression and controlled for ancestry (10 principal components), sex, age, and examination center. One locus on chromosome 17 met genome-wide statistical significance criteria—lead single-nucleotide polymorphism: rs11652874 (minor allele frequency = 0.06, intronic to* ASIC2 *[acid-sensing ionic channel 2, formerly named* ACCN1*]; odds ratio = 2.1, 95% confidence interval = 1.6 to 2.7,* P *=* 3.9×10^{-8}*). This association persisted among subjects with severe periodontitis and was robust to adjustment for microbial plaque index. Moreover, the minor (G) allele was associated with higher levels of severe GI in stratified analyses among subsets of participants with high load of either "red" or "orange" complex pathogens, although this association was not statistically significant. While these results will require replication in independent samples and confirmation by mechanistic studies, this locus appears as a promising candidate for severe GI. Our findings suggest that genetic variation in* ASIC2 *is significantly associated with severe GI and that the association is plaque independent.*

Knowledge Transfer Statement: *Persistent gingival inflammation reflected by bleeding usually precedes ongoing attachment loss or periodontal disease progression. Our findings suggest that genetic variation in* ASIC2 *that is associated with severe gingival inflammation might be used as a genetic marker to identify people at higher risk for periodontal disease. Ongoing studies to uncover the mechanistic link between* ASIC2 *and gingival inflammation could lead to novel therapeutic interventions.*

Keywords: periodontal disease(s)/periodontitis, gingivitis, genetics, genomics, plaque/plaque biofilms, bacteria

Introduction

Periodontal disease is an abnormal inflammatory response to the pathogenic bacteria present in the biofilm. Gingival inflammation (GI), as determined by bleeding upon probing, is a clinical hallmark for both gingivitis and periodontitis. Gingivitis affects >80% of Americans, while 47% of American adults have periodontitis (Eke et al. 2012). In addition to stress

exerted by the local microbial burden, it is now well-established that host genomics contributes to periodontal disease susceptibility. Twin studies by Michalowicz et al. (2000) suggested that heritability accounts for about 50% of the total phenotypic variability of periodontal disease. More recently, in a study of >10,000 Swedish twin pairs, Mucci et al. (2005) reported heritability estimates of 39% and 33% for women and men, respectively. In a more recent report, our group used a genome-wide association (GWA) approach to show that approximately 22% of phenotypic variance observed in severe chronic periodontitis can be explained by a GWA study (GWAS) set of approximately 650,000 genotyped single-nucleotide polymorphisms (SNPs) with minor allele frequency (MAF) ≥5% (Divaris et al. 2013).

Similar to other complex trait diseases, predisposition to periodontal disease is likely polygenic (Kinane et al. 2005). Most previous studies interrogating the genetic role in periodontal disease were based on a candidate-gene approach (Kornman et al. 1997; Tervonen et al. 2007; Kobayashi et al. 2009; Laine et al. 2012). GWASs provide an unbiased approach for generating hypotheses on nonrare genetic variants for common diseases, such as periodontitis. By the end of 2013, approximately 14,000 SNPs had reported GWAs with >600 traits (Welter et al. 2014). Although SNPs identified by GWAS may explain a small proportion of the observed variance for most diseases (Gibson 2010), this methodology has brought about notable successes in the study of obesity and metabolic traits (Locke et al. 2015). There is promise that similar advancements will eventually become possible in oral and periodontal research.

There are only a few GWASs on chronic periodontitis (Divaris et al. 2013; Teumer et al. 2013; Feng et al. 2014; Shaffer et al. 2014; Shimizu et al. 2015). While no significant genome-wide SNP hits have been identified so far, several suggestive loci have been reported. Divaris and colleagues (2013) reported the *NIN* locus as showing suggestive evidence of association with severe periodontitis. This locus was highlighted in a separate GWAS of periodontal disease by Shaffer et al. (2014), although the top SNP in the latter study was approximately 350 kb upstream of *NIN* and not in linkage disequilibrium with the lead SNP reported by Divaris et al. In addition, the *NPY* locus, which also emerged from the Atherosclerosis Risk in Communities (ARIC) study report, was subsequently highlighted by Freitag-Wolf et al. (2014) as being associated with periodontitis among men (albeit tagging SNPs were not in linkage disequilibrium), as well as by a gene-centric reanalysis of ARIC reported by Rhodin et al. (2014). Even fewer GWASs have explored loci associated with periodontal phenotypes defined by quantitative clinical signs rather than disease categories. Two notable exceptions include a study by Shaffer et al. (2014) that used probing depth ≥5.5 mm present in at least 2 sextants as the outcome for their GWA analyses and a study by Divaris et al. (2012) that reported several suggestive genetic loci associated with high bacterial pathogen colonization by "red" complex (*Porphyromonas gingivalis, Tannerella Forsythia*, and *Treponema denticola*), "orange" complex (*Prevotella intermedia, Fusobacterium nucleatum, Prevotella nigrescens*, etc.), and *Aggregatibacter actinomycetemcomitans* among European American participants of the ARIC cohort.

There is compelling evidence that persistent GI reflected by bleeding upon probing combined with residual probing depth after periodontal treatment has prognostic value for ongoing attachment loss or disease progression (Lang et al. 1986; Claffey et al. 1990; Matuliene et al. 2008). GI may also contribute to a systemic hyperinflammatory state that is etiologically related to other chronic diseases and pathologies (Scannapieco 2004). We do know that the microbial biofilm is etiologically associated with gingivitis (Loe et al. 1965). Yet, it is also known that inflammation, including the production of cytokines, is highly genetically regulated (de Craen et al. 2005). However, no systematic effort has been undertaken to study the genetic underpinning of GI as an independent clinical sign with a GWA approach. It is also unknown whether a genetic association, if present, is modified by the level of exposure to periodontal pathogens. We hypothesize that genetic variants that interact with known periodontal pathogens are associated with the severe GI trait as reflected by bleeding upon probing. To test this hypothesis, we used the well-defined Dental ARIC cohort and conducted the first GWA scan for genetic risk loci associated with extensive severe GI and examined these associations among subgroups with varying levels of subgingival periodontal pathogens and categorical classifications of chronic periodontitis.

Materials and Methods

Study Population and Measurements

We used data from the previously reported GWAS performed in a subset of European American subjects who were participants in the ARIC study (ARIC Investigators 1989). The ARIC cohort study aimed to study atherosclerosis, cardiovascular disease risk factors, and outcomes and originally recruited 15,792 community-dwelling residents in 4 U.S. communities between 1987 and 1989. As an ancillary study, Dental ARIC recruited a subset of ARIC participants in the fourth ARIC visit (1996-1998). During their dental visit, 6,017 dentate ARIC subjects had a complete full-mouth dental examination, which included measurements of probing depth, attachment loss, and bleeding upon probing at 6 sites per tooth, including third molars, number of missing teeth, and gingival index (Loe and Silness, 1963). Plaque index (PI) was recorded for each tooth according to the method introduced by Silness and Loe (1964). Subgingival plaque samples were also collected from 973 European American Dental ARIC participants. For the present analyses, we included only European

American participants and excluded individuals whose genotyping did not meet quality control criteria. Therefore, in this report we used genotype and clinical data from a subset of 4,077 Dental ARIC subjects.

Genotyping, Quality Control, and Imputation

Detailed description of genotyping and data processing were described elsewhere (Divaris et al. 2012; Divaris et al. 2013). Briefly, DNA was extracted from blood samples. Genotyping was performed with the Affymetrix Genome-Wide Human SNP Array 6.0 chip containing 906,600 SNP markers. After quality control, an imputation to 2.5 million SNP markers was performed with 669,450 high-quality genotyped SNPs and the MACH program (version 1.0.16) based on HapMap Phase II CEU build 36. Further SNP exclusion included the following criteria: imputation quality score <0.8, missing data rate >10% after imputation, and MAF <5%.

Quantification of Periodontal Organisms in Plaque Samples by DNA Checkerboard

Levels of bacteria within plaque samples were determined as previously described (Socransky et al. 1994). One plaque sample taken from the subgingival mesiobuccal site of the maxillary right first molar was used from each subject and hybridized to a DNA chromosomal checkerboard for the 8 periodontal pathogens present in the red or orange complexes defined by Socransky et al. (1998). Organism levels were expressed as counts based on known microbial standards. A "high" load was defined as those in the upper quartile (25%) range of counts, and a "low" load, those in the lowest three-quartiles count range. Eight periodontal pathogens were included for analyses: *Porphyromonas gingivalis, Prevotella intermedia, Treponema denticola, Tannerella forsythia* (formerly *Bacteroides forsythus*), *Campylobacter rectus, Fusobacterium nucleatum, Aggregatibacter actinomycetemcomitans* (formerly *Actinobacillus actinomycetemcomitans*), and *Prevotella nigrescens.*

Analytic Strategy

The clinical trait of interest was the extent of moderate to severe GI as reflected by the ordinal gingival index, wherein "0" reflects normal gingiva; "1," mild inflammation but no bleeding upon running probe in the sulcus; "2," moderate inflammation with bleeding upon running probe in the sulcus; and "3," severe inflammation with a tendency for spontaneous bleeding. Extent scores were calculated as the percentage of sites exhibiting gingival index ≥2 (EGIGE2) among all examined sites for each participant. The severe GI trait was defined dichotomously as gingival index extent score in the 90th percentile (top 10%), whereas the continuous GI variable was used for exploratory and stratified analyses. Genetic models were based on logistic regression, adjusting for ancestry (10 principal components), age, sex, and examination center. A conventional genome-wide significance level of $P < 5 \times 10^{-8}$ was used for single-marker discovery in the GWAS, whereas loci with suggestive evidence of association ($P < 5 \times 10^{-6}$) are also reported. All genetic analyses were performed with the ProbABEL software. We utilized Manhattan and LocusZoom plots (Pruim et al. 2010) to visualize the genetic loci of interest. We followed HUGO Gene Nomenclature to report genes. Exploratory analyses of the continuous GI trait, as well as analyses stratified by chronic periodontitis diagnosis and high versus low pathogen load, were based on generalized linear models, adjusting for ancestry, age, sex, examination center, and microbial plaque levels and accounting for multiple comparisons. We followed the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) checklist guidelines for the reporting of findings.

Results

Single-Marker GWAS

Genomic inflation for the severe GI association analysis was low ($\lambda = 1.008$). The quantile-quantile plot (Appendix Fig.) did not reveal any evidence of residual population stratification. The full list of GWAS results, including estimates of association for all 2.5 million SNPs, is available at http://genomewide.net/public/aric/dental/gingivitis/EGIGE2.txt. One locus on chromosome 17q11.2 met genome-wide statistical significance criteria (Fig. 1A) for the severe GI trait. The lead SNP in this locus was rs11652874: MAF (G) = 0.06, odds ratio (OR) = 2.1, 95% confidence interval = 1.6 to 2.7, $P = 3.9 \times 10^{-8}$. This imputed SNP has an imputation quality score of 0.998, which is considered excellent. This SNP is intronic to the *ASIC2* gene (acid-sensing ionic channel 2; previously named *ACCN1*; Fig. 1B), within the intron region between exons 2 and 3, and in tight linkage disequilibrium with 9 additional intronic SNPs (Fig. 1C). We found no association of this SNP with clinical diagnoses of chronic periodontitis (e.g., 4-level case definition per the Centers for Disease Control and Prevention / American Academy of Periodontology [CDC/AAP]; $P = 0.14$; Table). We found 3 additional loci with suggestive evidence of association ($P < 5 \times 10^{-6}$) with severe GI: *PHGDH* (lead SNP rs894049, $P = 1.2 \times 10^{-6}$, OR = 1.62, MAF [G] = 0.14), *NRXN1* (lead SNP rs1520455, OR = 1.47, $P = 4.0 \times 10^{-6}$, MAF [C] = 0.37), and *ACVR1* (lead SNP rs7578180, OR = 1.43, $P = 4.5 \times 10^{-6}$, MAF [C] = 0.33). *ASIC2* encodes a member of the degenerin/epithelial sodium channel superfamily and is likely involved in neurotransmission (Krishtal 2003).

Stratified Analyses

To further explore the *ASIC2* locus signal, we examined the lead SNP's association with the continuous GI trait (EGIGE2) stratified by the 4-level CDC/AAP chronic periodontitis diagnoses (Fig. 2). Not surprisingly, in both *ASIC2* genotype groups, EGIGE2 was higher among participants with more advanced (severe) disease status versus those with milder disease. We found no association between rs11652874 and EGIGE2 among

Figure 1. rs11652874 in the *ASIC2* gene locus is associated with severe gingival inflammation. (**A**) Manhattan plot of genome-wide association analysis results of severe gingival inflammation (binary trait based on EGIGE2q90) in the Atherosclerosis Risk in Communities cohort ($n = 4,077$). (**B**) Locus zoom visualization of the 17q11.2 locus (*ASIC2*, lead SNP: rs11652874) flanking ±400 kb. The vertical axis represents the $\log_{10}$-transformed *P* value for each SNP. A schematic representation of the *ASIC2* gene exons in relation to the lead SNP (rs11652874) is shown in the inset. (**C**) Locus zoom visualization of the 17q11.2 locus flanking a zoomed-in ±25-kb region. SNP, single-nucleotide polymorphism.

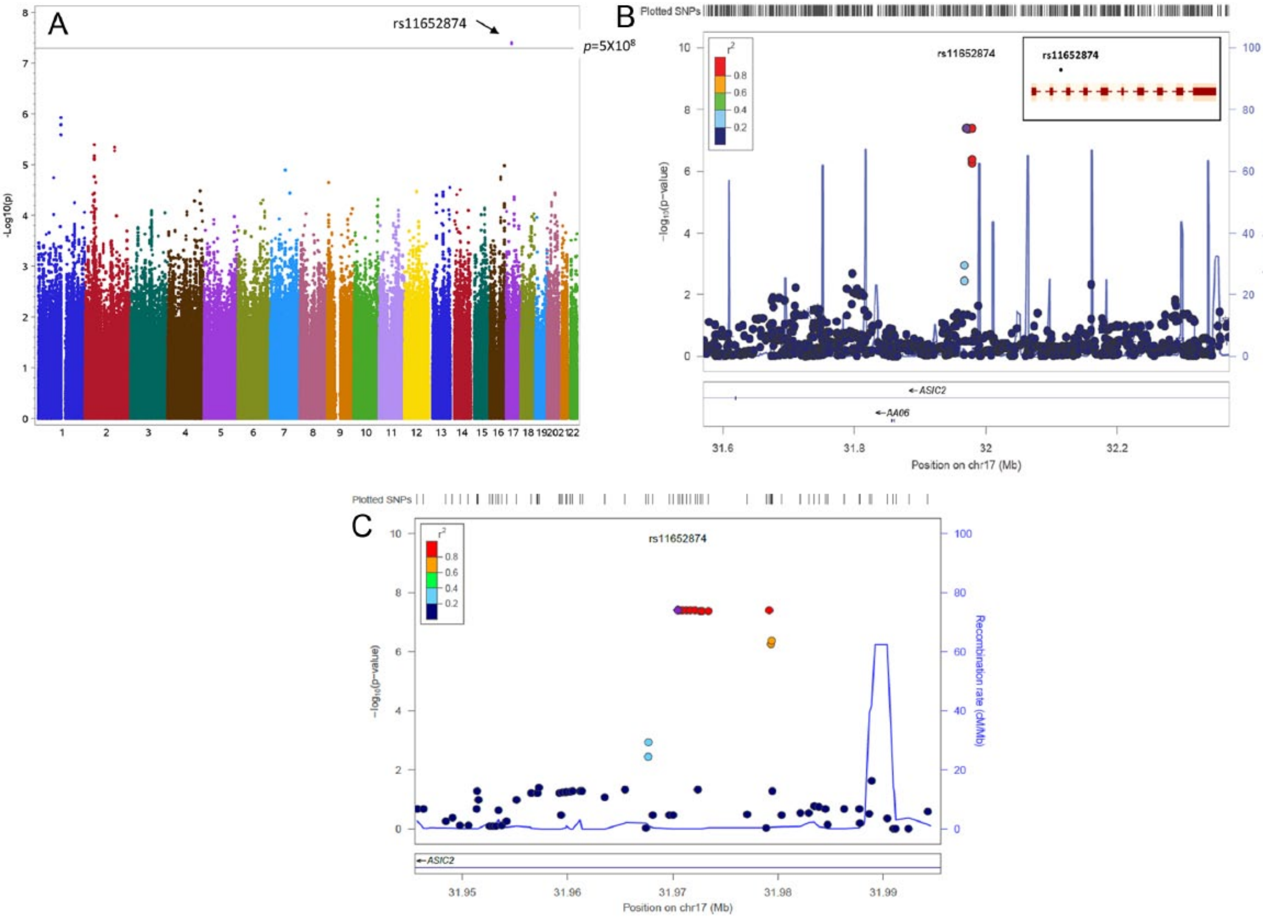

Table.

Genotype Distribution of rs11652874 according to Periodontal Disease Definitions.

Genotype	Periodontal Disease Definition, *n* (%)[a]				
	Healthy	Mild	Moderate	Severe	Total
C/C	492 (10.3; 11.7)	1,178 (24.7; 28.0)	1,817 (38.1; 43.2)	720 (15.1; 17.1)	4,207 (88.3; 100.0)
C/G+G/G[b]	67 (1.4; 12.0)	177 (3.7; 31.7)	214 (4.5; 38.3)	101 (2.1; 12.3)	559 (11.7; 100.0)
Total	559 (11.7)	1,355 (28.5)	2,031 (42.6)	821 (17.2)	4,766 (100.0)

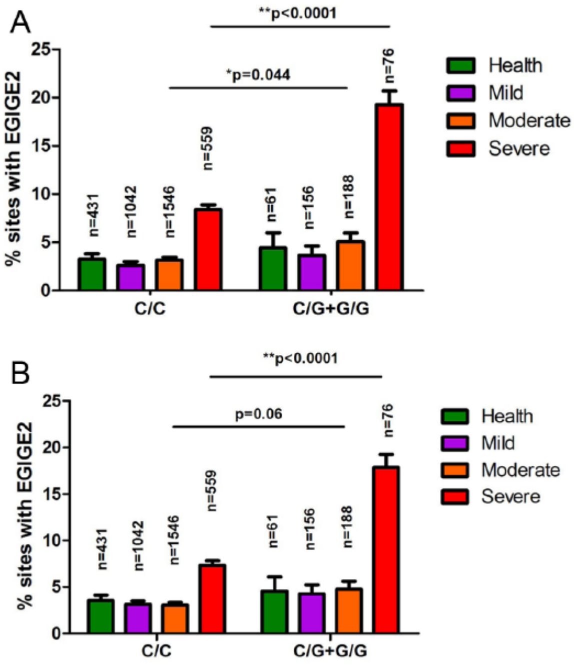
Four-level case definition based on the American Academy of Periodontology and Centers for Disease Control and Prevention (Eke et al. 2012).

[a] For cells that have 2 values in parentheses, the first value denotes the percentage among the entire sample, and the second, the percentage among subjects with the same genotype.

[b] $P = 0.14$ (χ^2 test).

subjects with periodontal health ($P = 0.67$) or mild periodontitis ($P = 0.13$). However, among subjects with moderate or severe periodontitis, the EGIGE2 is significantly higher among rs11652874 (G) allele carriers versus noncarriers ($P = 0.04$ for moderate periodontitis and $P < 0.0001$ for severe periodontitis) after adjustment for study design features,

Figure 2. Association of rs11652874 polymorphisms (minor allele [G] carriers vs. noncarriers) with gingival inflammation extent score ≥2 (EGIGE2) stratified by chronic periodontitis diagnosis (case status classification per the American Academy of Periodontology and Centers for Disease Control and Prevention), adjusting for (**A**) age, sex, ancestry (10 principal components), and examination center and (**B**) microbial plaque levels, age, sex, ancestry (10 principal components), and examination center.



participant characteristics, and ancestry (Fig. 2A). This association was somewhat attenuated after further adjustment for plaque score (Fig. 2B) in the moderate periodontitis stratum (unadjusted: beta = 1.92, $P = 0.04$, vs. adjusted: beta = 1.69, $P = 0.06$), whereas it remained significant ($P < 0.0001$) in the severe periodontitis stratum. In other words, the increased GI among those with the *ASIC2* minor (G) allele polymorphism was not substantially affected by microbial plaque levels, particularly among participants with severe chronic periodontitis.

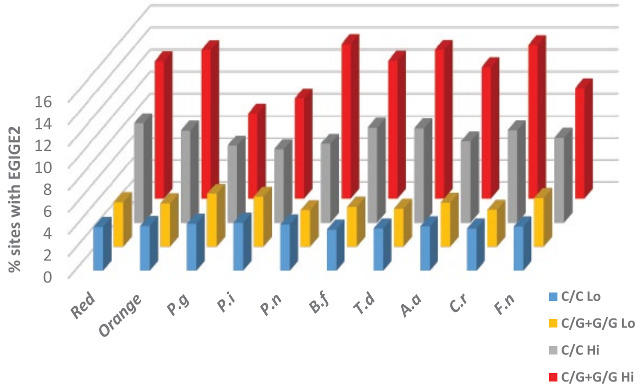
To further explore the possible effect modification by microbial plaque, next we examined possible SNP × periodontal pathogen interactions that might account for the higher gingival index score. Therefore, we examined whether rs11652874 (G) allele carrier status modified the gingival inflammatory response to bacteria of the red and the orange complexes, as well as individual bacterial species. High periodontal pathogen loads were associated with statistically increased gingival index scores as compared with lower bacterial loads, independent of rs1652874 genotype (Fig. 3; *P* values not shown). Although a trend for an association between rs1652874 (G) allele and periodontal pathogen levels was noted, we found no statistically significant association after adjustment for multiple comparisons.

Discussion

In this genome-wide investigation conducted among the well-defined Dental ARIC cohort, we found a novel locus associated with severe GI. The identified polymorphism is intronic to the *ASIC2* gene and not associated with CDC/AAP chronic periodontitis diagnosis. The rs11652874 minor (G) allele was associated with the most severe gingival bleeding among those with severe chronic periodontitis, and this was independent of microbial plaque levels. We tested the hypothesis that levels of specific periodontal microorganisms may alter the clinical response according to the *ASIC2* polymorphism. Although some trends were noted, the extent of GI was not associated with this polymorphism within red or orange pathogen high- and low-load groups. These findings suggest that there may be additional loci or biological or environmental/behavioral risk factors that are specific to severe disease and interact to produce extremely high gingival index scores (Manolio et al. 2009).

The lead SNP in the *ASCI2* locus is located in the gene's second intron of the gene. Acid-sensing ion channels play an important role in the nervous system (Lingueglia and Lazdunski 2015). We found no important functional annotation or expression quantitative trait loci information about this SNP in publicly available databases such as SNPnexus (http://snp-nexus.org/) and GTEx (http://www.gtexportal.org/). *ASIC2* has been reported to be ubiquitously expressed in the mammalian peripheral and central nervous system. Residing in the free sensory nerve endings that are in contact with local tissue, this molecule may regulate the physiologic response of microvessels to fluctuations of local oxygen consumption. During inflammation, the drop of pH due to increased oxygen utilization leads to *ASIC2* activation and the release of vasoactive substances from the other branches of nerve endings is triggered (Krishtal 2003). The involvement of *ASIC2* in inflammation is supported by experiments with *ASIC2* knockout mice, in which several inflammatory markers, such as TGF-β (transforming growth factor-β) and TAPA-1 (target of antiproliferative antibody 1), were all upregulated when compared with wild-type controls (Gannon et al. 2015). Although there is evidence supporting a plausible role for *ASIC2* contributing to gingival hyperinflammatory phenotype, further replication and mechanistic studies are warranted for its validation.

Figure 3. Comparison of severe gingival inflammation extent scores (EGIGE2) by levels of 8 periodontal pathogens in the red and orange complexes as determined by DNA checkerboard; bacterial loads were dichotomized into high level (the top quartile) and low level (lowest 3 quartiles) and stratified by genotypes at rs11652874. *A.a, Aggregatibacter actinomycetemcomitans* (formerly *Actinobacillus actinomycetemcomitans*); *B.f, Tannerella forsythia* (formerly *Bacteriodes forsythus*); *C.r, Campylobacter rectus; F.n, Fusobacterium nucleatum; P.g, Porphorymonas gingivalis; P.i, Prevotella intermedia; P.n, Prevotella nigrescens; T.d, Treponema denticola*.



The neurotransmitter and nervous system signaling pathways have been repeatedly reported in our GWASs and others, as well as in our transcriptome studies (Offenbacher et al. 2009; Divaris et al. 2013). The exact role of neuropathways in periodontal health and disease remains to be elucidated; nevertheless, neuropeptides are known to regulate acid-sensing ion channels, as detailed by Vick and Askwith (2015). Ingenuity pathway analyses based on data from our experimental transcriptome gingivitis study indicate that there are 4 genes upstream to *ASIC2* that are upregulated during gingivitis induction (*ASIC2* was not present on our transcriptome array for scanning), suggesting the activation of inflammatory pathways involving *ASIC2*. These genes are *NRXN1, CHD8, CTNNB1*, and *NLGN1* (Offenbacher et al. 2009). Noteworthy, several chemokine genes, including *CCL2, CCL8, CCL11, CCL7*, and *CCL13*, are located downstream of *ASCI2* on chromosome 17q12. The involvement of those CCL chemokines in periodontal inflammation is well documented (Silva et al. 2007). The signal in the *ASIC2* locus may also highlight other possibly associated genes in nearby genome regions, and these chemokine genes would serve as excellent additional candidates.

In addition to *ASIC2*, we identified several suggestive loci close to genes with known functions. For example, rs894079 is located in the 5′ untranslated region of *PHGDH*, which encodes the enzyme involved in the early steps of L-serine synthesis in animal cells (Zogg 2014). Rs1520455 is intronic to *NRXN1*, which encodes neurexin, a presynaptic protein diffusely distributed in neurons and a key component in neuronal network (Bottos et al. 2011). Rs7578180 is intronic to *ACVR1*, which encodes a receptor for activins, which are dimeric growth and differentiation factors belonging to the TGF-β superfamily of signaling proteins (Goumans et al. 2003). Although those SNPs did not meet criteria for genome-wide statistical significance, they appear as promising candidates for future studies.

Our study is limited by the absence of a replication sample to externally validate the observed association between rs11652874 and GI. Although our results are derived from a moderately sized GWAS, including >4,000 community-dwelling participants in a well-defined cohort, an independent replication of this SNP and other polymorphisms highlighted in this study is warranted. We acknowledge that independent replication and mechanistic validation are crucial because this association—although statistically robust—may simply represent a false-positive finding (Ioannidis 2005). Moreover, we considered levels of only 8 key pathogens within the red and orange complexes and cannot exclude that other organisms unique to the moderate and severe disease states might be critical and interact with this polymorphism to produce high levels of GI. For example, we and others have reported on the importance of organisms such as *Fretibacterium* and *Treponema* species in periodontal disease (Marchesan et al. 2015). This recent Human Microbiome Identification Microarray study identified 272 subgingival microbial species and defined *Synergistetes*- and *Spirochaetes*-dominated microbial community structures that were significantly associated with increased probing depth and bleeding upon probing (Marchesan et al. 2015). Those pathogens and many other important organisms were not included in analyses presented here, which were limited to the key "classical" cultivable pathogens.

In summary, in these GWA analyses of severe GI among the Dental ARIC European American population we found a genome-wide significant association of a chromosome 17q12 locus, marked by a SNP intronic to the *ASIC2* gene. The association persisted among groups with severe periodontitis and was independent of clinical levels of microbial plaque; neither loads of specific red or orange complex pathogens modified this association. These results provide support for the conduct of further studies in this or nearby genome regions to explore if and how common genetic variation in *ASIC2* plays a role in severe GI.

Genetics and Genomics of Addiction

Jason A. Bubier

The Jackson Laboratory, Bar Harbor, ME 04609, USA; jason.bubier@jax.org

Substance use disorders (SUD), like many neuropsychiatric conditions, are a heterogeneous group of disorders with similar symptomatology but often different pathoetiology. As diagnosed by the DSM-V, SUD requires at least two of eleven diagnostic criteria, resulting in the possibility of over 2000 different combinations of symptoms. Further segmenting the disorder is that SUD can involve a variety of legal and illegal substances. There are currently approaches to treating and managing SUD, but we have a limited armamentarium. Genetic and genomic studies of addiction can facilitate a more accurate molecular diagnosis and, ultimately, the development of appropriate treatments. Sequenced genomes, new animal model resources, and Genome Wide Association Studies (GWAS) of large sample sizes have made vast inroads into our understanding of the genetics that underlies addiction. Future mechanistic studies will be driven by integrating big data from animal models and human studies to identify their consilient features. This Special Issue, "Genetics and Genomics of Addiction," focuses on genetic contributions to this disease that may lead to better-targeted therapeutics and diagnostics. This issue contains five original research articles and one review paper that furthers our collective knowledge of SUD disease etiology and the genetic risk factors underlying the disease.

Chunduri, Watson and Ashbrook explore how the controlled laboratory environments of animal model research can be leveraged to understand the gene-by-environment (GxE) interactions underlying SUD [1]. Their work relies on the recombinant inbred population of the BXD strains of mice, which have reproducible genomes that can be tested in different laboratory environments, allowing one to make novel insights into GxE. They illustrate that this can be accomplished using GeneNetwork.org, a database and tool suite containing over 10,000 phenotypes and over 100 'omics datasets measured under various environmental conditions derived from the BXD panel. The group reanalyzed data published in 2010 using new mapping software and complete genomic sequence and identified novel candidate genes involved in response to drug use. Also, using model organisms, Rizk et al. [2] explored the impact of sex and circadian disruption on alcohol drinking in mice. Utilizing both sexes of *Clock* mutants, the researchers assessed alcohol consumption and preference. As expected, female control inbred C57BL/6J mice drank more than the males. However, there were no sex differences in the *Clock* mutants, which displayed greater alcohol preference and consumption over controls of both sexes. Studies like these illustrate how the environment and circadian disruption can affect SUD. The final article in this collection utilizing animal models was the work of Lie et al. [3] in which the authors set out to determine the relationship between methylation of the guanine nucleotide-binding protein, α stimulating complex locus, (*Gnas)* promoter, *Gnas* mRNA levels and morphine reward memory. Hypermethylation of the *Gnas* promoter and decreased mRNA expression in the basolateral amygdala were necessary for reconsolidating opiate-associate memories. A review paper by Sambo and Goldman [4] summarizes the current knowledge around the role of genetic influence in Fetal Alcohol Spectrum Disorder (FASD). This SUD-adjacent field of study explores the range of outcomes that result from prenatal alcohol exposure. The human literature related to twin studies, copy number variations, and candidate gene studies, illustrates a role for various genetic factors in FASD susceptibility. Fedorenko et al. [5] also explored alcohol use, assessing the association of phosphatidylinositol-5-phosphate-4-kinase type two α (PIP4K2A) polymorphisms with alcohol use disorder. Polymorphisms

in PIP4K2a, a gene known to play a role in dopaminergic pathways, were tested for their association with AUD in a population of Russian men. In this case-control study, two PIP4K2A SNPs had a higher association of occurring in cases than in controls, suggesting that different PIP4K2A polymorphisms may be associated with an increased risk of AUD. The final paper in this collection, that of Chmielowiec et al. [6], also performed case-control studies looking at the associations of polymorphisms in the dopamine transporter (DAT1) with new psychoactive substance use. New psychoactive substances are drugs designed to mimic established drugs, such as cannabis, cocaine, MDMA and LSD [7]. Their conclusion supported a role for certain DAT1 polymorphisms being associated with higher levels of neuroticism and new psychoactive substance use.

This special issue aimed to bring together researchers of substance use disorder across various drugs of abuse and experimental systems to describe the current status of addiction genetics. Psychiatric disorders are known to be complex traits due to their polygenic nature. The articles in this special issue covered various topics and provided diverse insights to direct future SUD genetics research. The growing number of pathways, genes, proteins, and molecules that appear to be involved in SUD is of special interest. We anticipate that this Special Issue will help researchers search for additional genetic associations that will help refine our understanding of the etiology of this complex disease.

Genomic comparative analysis and gene function prediction in infectious diseases: application to the investigation of a meningitis outbreak

Enrico Lavezzo[1], Stefano Toppo[1], Elisa Franchin[1,2], Barbara Di Camillo[3], Francesca Finotello[3], Marco Falda[1], Riccardo Manganelli[1,2], Giorgio Palù[1,2*] and Luisa Barzon[1,2*]

Abstract

Background: Next generation sequencing (NGS) is being increasingly used for the detection and characterization of pathogens during outbreaks. This technology allows rapid sequencing of pathogen full genomes, useful not only for accurate genotyping and molecular epidemiology, but also for identification of drug resistance and virulence traits.

Methods: In this study, an approach based on whole genome sequencing by NGS, comparative genomics, and gene function prediction was set up and retrospectively applied for the investigation of two *N. meningitidis* serogroup C isolates collected from a cluster of meningococcal disease, characterized by a high fatality rate.

Results: According to conventional molecular typing methods, all the isolates had the same typing results and were classified as outbreak isolates within the same *N. meningitidis* sequence type ST-11, while full genome sequencing demonstrated subtle genetic differences between the isolates. Looking for these specific regions by means of 9 PCR and cycle sequencing assays in other 7 isolates allowed distinguishing outbreak cases from unrelated cases. Comparative genomics and gene function prediction analyses between outbreak isolates and a set of reference *N. meningitidis* genomes led to the identification of differences in gene content that could be relevant for pathogenesis. Most genetic changes occurred in the capsule locus and were consistent with recombination and horizontal acquisition of a set of genes involved in capsule biosynthesis.

Conclusions: This study showed the added value given by whole genome sequencing by NGS over conventional sequence-based typing methods in the investigation of an outbreak. Routine application of this technology in clinical microbiology will significantly improve methods for molecular epidemiology and surveillance of infectious disease and provide a bulk of data useful to improve our understanding of pathogens biology.

Keywords: *Neisseria meningitidis*, Whole genome sequencing, Next generation sequencing, capsule locus, Comparative genomics, 454 pyrosequencing, Meningitis outbreak, Molecular epidemiology, Gene function prediction

Background

The recent success of next generation sequencing technologies (NGS), that are now available in many laboratories and sequencing centers, is deeply impacting our capability to investigate biological samples in many fields of research, including microbiology and virology [1,2]. In this regard, the main applications fostered by NGS are the identification of novel pathogens, the metagenomics analysis of biological and environmental niches, the investigation of transcriptomes, and the characterization of full-length microbial and viral genomes for a wide range of purposes, including phylogenetic and epidemiological studies and the characterization of drug-resistant or immune-escaping mutants [3-6].

For each of these applications, a plethora of bioinformatics tools is available, both academic and commercial, that has to be applied and coordinated depending on the specific needs. In this study we report the application of an analysis pipeline which combines genomic comparative

analysis and gene function prediction to finely characterize microbial genomes. The pipeline was applied to the retrospective analysis of a group of *Neisseria meningitidis* isolates collected during an outbreak. Epidemiological, clinical, and surveillance data on this outbreak, which occurred in north-eastern Italy during the 2007–2008 winter and was characterize by a high fatality rate, have been previously reported [7,8]. The results of this study highlight the essential contribution of whole genome sequencing, performed by NGS technology, to distinguish outbreak cases, i.e., related cases with a common epidemiological source, from clusters of temporary and geographically proximate but unrelated cases. In addition, genomic comparative analysis and gene function prediction led to the identification of genetic changes in the capsule locus that could have contributed to pathogenicity.

Methods

N. meningitidis isolates

N. meningitidis isolates of an outbreak which occurred in Veneto Region (north-eastern Italy) in December 2007-January 2008 were collected by local hospital laboratories and sent to the Regional Reference Laboratory at Padua University Hospital for confirmation, phenotypic characterization, and molecular typing. The outbreak strains analyzed in the present study included *N. meningitidis* isolates from seven patients (mean age 23 year, range 15–33 years) from a relatively small geographical area, who had disease onset between December 13, 2007 and January 4, 2008.

The study was approved by the Ethics Committee of Padova University Hospital (protocol no. 53503).

Phenotypic and genotypic characterization of *N. meningitidis* isolates

Serogrouping, which was performed by slide agglutination using commercial antisera (Remel Europe Ltd, Dartford, UK), classified all the 7 isolates as serogroup C. All isolates were fully susceptible to penicillin, rifampicin, ceftriaxone, and ciprofloxacin. Pulsed-field gel electrophoresis analysis gave the same electrophoresis pattern for all isolates, indicating their relatedness. Molecular characterization by MLST, performed according to Maiden *et al.* [9], demonstrated that all isolates belonged to the same sequence type and clonal complex ST-11 (all isolates had the following MLST alleles: *abcZ* 2, *adk* 3, *aroE* 4, *fumC* 3, *gdh* 8, *pdhC* 4, *pgm* 6). In addition, sequencing of *N. meningitidis PorA* variable regions 1 and 2 [10] confirmed that all isolates had the same *PorA* subtype 5–1, 10–8.

Whole genome sequencing of *N. meningitidis* isolates by 454 pyrosequencing

Whole genome sequencing of two *N. meningitidis* isolates, the index case (named K1207) and the last case (named S0108) of the outbreak, was performed with the objective of confirming their relatedness and to detect genetic differences between the two strains that could have occurred during the short period of the outbreak. The draft genome sequences of these two *N. meningitidis* isolates were reported in a previous announcement [11].

Genomic DNA was purified from meningococcal isolates using a phenol-chloroform-based method.

Sequencing was performed using a Roche 454 Life Sciences Genome Sequencer FLX platform following the manufacturer's instructions (Roche 454 Life Sciences, Branford, CT, USA). For each sample, 2 different libraries were prepared, a shotgun and a 3 kb paired-end, starting from 5 μg of genomic DNA. The shotgun library was prepared as follows: after nebulization, purification and adaptors ligation, DNA fragments were clonally amplified using the Emulsion PCR Kit I (Roche). For the preparation of the paired end library, genomic DNA was fragmented by hydrodynamic shearing, followed by a size selection step, hairpin adaptors ligation and circularization of fragments. From this step the procedure was similar to the shotgun one, consisting in the nebulization of circular molecules, paired end adaptors ligation and amplification of the library. The clonal amplification was carried out using the Emulsion PCR Kit II (Roche). Sequencing was performed on a GS FLX instrument, using the Standard LR70 Sequencing Kit (Roche). Images were processed using the runAnalysisPipe and runAnalysisPipePairedEnd commands provided with the DataProcessing package (Roche). With respect to the previous genome announcement [11], we performed a new *de novo* assembly with the most recent version of the Newbler software (v.2.6), which is more effective and produces a smaller number of contigs with respect to older versions [12].

Gene identification and comparison between the two *N. meningitidis* genomes and comparison with FAM18 reference genome

The assembled sequences of K1207 and S0108 isolates were compared to each other and with the most similar genome among those already available in RefSeq database, i.e., the FAM18 strain genome (NC_008767). Whole genome level comparison was made with MUMmer3.23 package, to investigate possible large recombination events.

To compare the CDS content between K1207 and S0108 genomes an approach to find the reciprocal blast best hits was implemented. This method is widely used to identify the coding sequences that are supposed to be "orthologs". The following steps were performed:

– download of protein sequences of genes annotated on each of the following complete *N. meningitidis* genomes, spanning different serogroups: FAM18 (NC_008767) and 053442 (NC_010120) from serogroup C, Z2491 (NC_003116) from serogroup

A, MC58 (NC_003112) from serogroup B and the capsule null strain alpha14 (NC_013016), for which the serogroup cannot be defined.
- clustering of protein sequences from the previous step at 90% of sequence identity, using cd-hit [13,14], in order to eliminate redundancy and create a reference proteome.
- *de novo* gene prediction on isolates K1207 and S0108 using Glimmer3.02 [15] and extraction of the corresponding protein sequences.
- search of protein sequences belonging to each isolate against this reference proteome using blastp [16]; since all analyzed protein sequences belong to the same species, only matches with at least 90% of sequence identity and covering at least 90% of sequence length were considered. The threshold was chosen after testing different cutoff values: relaxing this parameter did not produce substantial changes in the number of shared CDSs, while tightening the percentage identity cutoff resulted in a rapid decrease in the number of shared CDSs (see Additional file 1: Figure S1). Nonetheless, this high stringency led to the loss of many similar genes whose function is identical.
- starting from blastp output, a table of matches was created in which, for each protein, “0” or “1” indicated its absence or presence in the different genomes. From this table it was possible to extract different lists of genes, common to both genomes, or specific to one or another.

To better characterize the differences between the two isolates, function prediction of unknown genes was done:

- genes with unknown function were analyzed by means of the function prediction tool Argot2 [17-19]. This algorithm was developed by our bioinformatics group and allows to retrieve scored GO annotations for a given gene or CDS, starting from its nucleotide or protein sequence.

The workflow of the analysis pipeline is summarized in Figure 1.

Validation of genetic differences among *N. meningitidis* isolates by target-specific PCR and cycle sequencing

Some of the genes found to be present in only one of the two *N. meningitis* isolates were selected for validation with target-specific PCR and conventional cycle sequencing. A detailed list of investigated genes is reported in Table 1, along with brief gene function descriptions. These genes were also screened in the other five *N. meningitidis* isolates from the outbreak and in sporadic *N. menigitidis* isolates, with identical multilocus sequence type and *porA* genotype, which were collected in Veneto Region in 2007 and 2008.

Results

Pyrosequencing results

The index and the last cases of a *Neisseria meningitidis* outbreak, named K1207 and S0108 respectively, were sequenced in a 454 FLX platform. For K1207 genome, a total of 257,909 shotgun reads were obtained, with average length of 237 bases, and 63,593 paired end reads with an average distance of 3,113 nucleotides. For genome S0108, the shotgun reads obtained were 241,983 with an average length of 235 bases, while paired end reads were 50,658 with an average distance of 2560 bases. The average depth was 27 to 28 fold for both genomes. Raw reads were assembled with Newbler2.6.

Characteristics of sequenced genomes and plasmids of *N. meningitidis* isolates

The genome sequences of the two *N. meningitidis* serogroup C ST-11 isolates were very similar to *N. meningitidis* serogroup C FAM18 strain, which is a representative of the ST-11/ET-37 clonal complex and whose sequence is completely finished and deposited in RefSeq (NC_008767). A deeper analysis revealed that the two isolates belonged to the ET-15 variant of the ST-11 complex, as demonstrated by the presence of the IS*1301* insertion element [20] and the ET-15 fumarate hydratase gene [21].

The sequence of a 7-kb plasmid, identical in both isolates and very similar to pJS-B (RefSeq accession number NC_004758) was also obtained. Draft genome sequences have been deposited in GenBank (accession numbers ADWM02000000 and ADWN02000000 for K1207 and S0108, respectively).

Comparison of *N. meningitidis* serogroup C genomes through analysis of their coding sequence content

To screen for the presence of genetic variations between the two isolates, the K1207 and S0108 genomes were compared by assessing their coding sequence (CDS) content, looking for shared and genome-specific CDSs. The latter were defined as CDSs for which a reciprocal match between the two isolates was not detected. Following the criteria described in the methods section, 2011 CDSs were identified as present in both genomes, 11 CDSs were exclusively present in K1207 genome, while 10 CDSs were present in S0108 genome only. Since most unique CDSs encoded hypothetical proteins of unknown function, we performed a function prediction step by using Argot^2 webservice, an in-house developed tool [17-19]; the complete report of predicted functional annotations is available in Additional file 1: Figure S1. These genes were predicted to encode proteins belonging to the membrane compartment, involved in capsular polysaccharide biosynthetic process, or adhesins and transport proteins.

Figure 1 Analysis algorithm. Diagram of the analysis workflow applied to the investigation of a meningitis outbreak based on genomic comparative analysis and gene function prediction.

Screening for genetic differences in other *N. meningitidis* serogroup C ST-11 isolates of the outbreak

Since the dissimilarities between the two *N. meningitidis* isolates could be the result of genetic variations of the same strain within the outbreak, we selected a subset of these differences for further investigation and validation by using target-specific PCR and cycle sequencing. This analysis was performed in the two sequenced *N. meningitidis* K1207 and S0108 strains for confirmation and in the other five isolates of the outbreak (i.e., isolates B-F in Table 1), as well as in other two ST-11 isolates (i.e., isolates A and G in Table 1), which were collected from sporadic meningitis cases that occurred in the same area in November 2007 and in April 2008. The results of this analysis confirmed findings provided by NGS and bioinformatics comparison for the K1207 and the S0108 isolates and, unexpectedly, they demonstrated that the S0108 isolate did not belong to the outbreak cluster. In fact, while the other five isolates from the same outbreak shared the same sequences of the outbreak index case K1207, the CDSs of S0108 were found in the strains isolated from sporadic meningitis cases, but differed from those of the outbreak isolates (Table 1). Thus, these results demonstrate that the outbreak was caused by the K1207 strain, while the S0108 strain was circulating in the same region during the same season and caused sporadic meningitis cases.

Analysis of the capsule locus

Comparison among K1207, S0108, and FAM18 *N. meningitidis* genomes at whole genome level and for CDS content demonstrated that most genetic variations occurred in the capsule locus. The results of whole genome comparison between K1207 and S0108 are illustrated in Figure 2, where an inversion in the capsule locus of S0108 is demonstrated. The whole genome alignment is shown with a dot plot matrix, where a dot is drawn each time there is a match between two regions of the genomes. Ideally, a perfect alignment would result in a continuous diagonal line from the start to the end of genomes; the presence of a chromosome inversion is highlighted by a break in the diagonal, with the change in dots direction indicating an inverse complement alignment. A map summarizing genetic changes among K1207, S0108 and FAM18 genomes is shown in Figure 3, where the blue chiasma indicates the same inversion present in S0108 with respect to FAM18.

The K1207 genome had remarkable changes in CDS content and nucleotide sequence of the capsule locus in comparison with both S0108 and FAM18 strains, which were consistent with multiple events of recombination and horizontal gene transfer. Genetic variations in the capsule locus of K1207 affected (i) the *refB* gene, which had a deletion in 3′, (ii) the duplicated *galE-rfbBAC* operon (for lipooligosaccharide biosynthesis) and the downstream *lipAB* operon (for phospholipid modification of the capsular polysaccharide, required for its translocation to the cell surface), which had genes with markedly different nucleotide sequences and the insertion of novel CDSs (i.e., *SacB*, which we predicted to encode a polysaccharide phosphotransferase, and rfbC/D which encodes a TDP-deoxymannose-dehydratase); (iii) and the *oatC* gene (that encodes polysialic acid-specific O-acetyltransferase), which was interrupted by the insertion of a mobile element of the

+ present, by PCR; - not present, by PCR.

The target CDSs that were specifically detected in the K1208 and S0108 genomes by 454 pyrosequencing were validated by means of PCR and Sanger sequencing. Then, they were searched also in *N. meningitidis* isolates A-G, which represent all the *N. meningitidis* serogroup C isolates classified as ST-11/ET-15 that were collected in Veneto Region in 2007–2008. Isolates B-F show the same pattern of K1207 and are classified as “outbreak cases”; isolates A and G are sporadic cases and are similar to S0108.

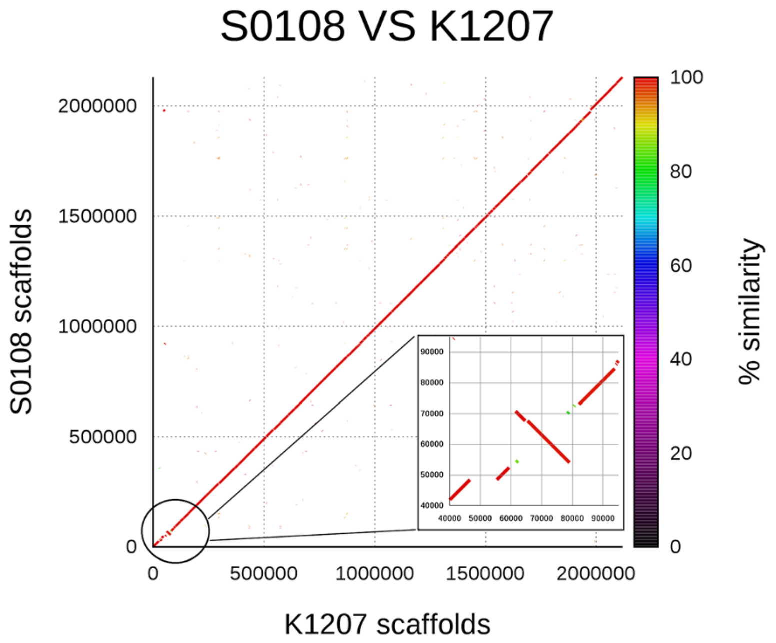

Figure 2 Genome-wide comparison of samples K1207 and S0108. Whole genome alignment between isolate K1207 vs. isolate S0108. The inset highlights the 20 Kb inversion in the capsule locus region between the two isolates. The dot plot was generated with MUMmer3.23 (http://mummer.sourceforge.net) and indicates matching sequences in forward and reverse direction.

IS4 transposase family. Search in the GenBank database demonstrated that the *SacB* gene was present only in the genome of the carriage *N. menigitidis* strain alpha275 (Genbank AM889138), but not in pathogenic strains. In addition, we found this gene also in *Neisseria mucosa*, suggesting that the rearranged region of the capsule locus in K1207 might have been acquired by horizontal gene transfer from nonpathogenic meningococci or other commensal *Neisseria* species.

The CDS content of the S0108 genome showed a high degree of similarity with FAM18 genome, with the exception of a large inversion in the capsule locus of a region of approximately 20 Kb included between the duplicated *rfbC* and *rfbC2* genes (Figures 2 and 3). In addition, the

Figure 3 Capsule locus modifications. Map of the capsule locus of K1207 and S0108 *N. meningitidis* isolates in comparison with FAM18 strain. Changes in CDS content between K1207 and FAM18 are highlighted in yellow, with the percentage similarity of amino acid sequences reported in parenthesis; the 20 kb inversion in the S0108 genome is indicated in blue.

nucleotide sequence of the *rfbC2* gene in the FAM18 genome was different from the corresponding gene in K1207 and S0108 genomes.

Discussion

In this study, an approach based on whole genome sequencing by NGS technology, comparative genomics, and gene function prediction was set up and applied to investigate *N. meningitidis* isolates, collected during an outbreak, that appeared identical by standard molecular typing methods based on PFGE, MLST, and *porA* VR1/VR2 sequencing. Whole genome sequencing demonstrated genetic changes between the fully sequenced isolates: then, a specific PCR based strategy applied to other samples from the same outbreak, followed by Sanger sequencing, allowed to distinguish outbreak cases from other temporal and geographically proximate but unrelated cases. This approach was designed in order to be feasible with a small budget. Nonetheless, the continuous decrease of sequencing costs, due to the improvement in the throughput of existing sequencing platforms and the simultaneous development of new technologies, will probably foster a wider employ of next generation sequencing in diagnostics and surveillance activities.

Comparative genomics analysis led to the identification and characterization of genetic differences among strains that might have been relevant for virulence and pathogenicity. In fact, in comparison with the *N. meningitidis* serogroup C ST-11/ET-37 reference strain FAM18 and with the S0108 isolate, the hyper-virulent K1207 outbreak isolate had marked changes in the capsule locus, consistent with recombination and horizontal acquisition of a set of genes involved in capsule biosynthesis from other meningococci. Although experimental verification is required, we hypothesize that these genetic changes might have enhanced transmissibility and invasiveness or even changed antigens involved in host immunity. In this regard, acquisition of novel genotypes at antigen-encoding loci has been reported to be probably the mechanism of emergence of hyper-virulent *N. meningitidis* ST-11 complex strains [22].

Homologous recombination and horizontal gene transfer are quite common in pathogenic *N. meningitidis* strains [23] and frequently affect virulence genes, including the capsule biosynthesis locus which may cause capsule switching [24], genes targeted by vaccines, and antibiotic susceptibility genes [25]. Considering this high variability, the conventional genotyping methods that are used to investigate outbreaks and to monitor the circulation of new variants of hyper-virulent strains may not be accurate enough. Several recent studies have demonstrated the power of whole genome sequencing by NGS technology to improve the identification of the geographical and evolutionary origin of an outbreak and to distinguish cases that belong to the outbreak from cases that do not [26].

The application of NGS technologies for the investigation of outbreaks in real time is becoming feasible thanks to the development of semi-automatic pipelines, as proposed in some recent publications [27-29]. In particular, Vogel *et al.* [27] demonstrated how to apply NGS in clinical practice, focusing on target genes of conventional typing methods (i.e., MLST, *porA* and *fetA* typing) and antimicrobial resistance gene testing (i.e., *penA* and *rpoB*). This approach can be expanded, as shown by Jolley *et al.* [28,29], on different subsets of genes, including the standard MLST loci, the ribosomal genes, personalized lists of specific loci, and whole sets of loci annotated on a complete reference genome. Such tools, which come along web platforms and interactive easy-to-use interfaces, are certainly essential instruments that will allow the introduction of whole genome sequencing in diagnostic routine. Instead, a limitation of their application in research is the capability to identify new determinants, not yet known and annotated [3]. The function prediction step integrated in our approach can provide valuable information to improve our understanding on unknown features, such as horizontal gene transfer and genome rearrangements. Though requiring experimental validation, these predictions could be useful to drive the experimental design and produce annotations: this new information will, on the one hand, enrich public databases and increase our knowledge about bacterial biodiversity and pathogenic mechanisms, and on the other hand it will be available for future routine diagnostic access.

Conclusion

In conclusion, this study represents a practical example on the application of NGS technology to the investigation of an outbreak and how this technology may be helpful in the identification of outbreak cases with a direct clinical impact on the containment measures being taken. This study also shows how the avalanche of genomic information provided by NGS technology and bioinformatics analysis may contribute to our understanding of human pathogens.

Genomic medicine for kidney disease

Emily E. Groopman, **Hila Milo Rasouly**, and **Ali G. Gharavi**
Division of Nephrology, Columbia University College of Physicians and Surgeons, 1150 Saint Nicholas Avenue, Russ Berrie Pavilion #412C, New York, New York 10032, USA.

Abstract

Technologies such as next-generation sequencing and chromosomal microarray have advanced the understanding of the molecular pathogenesis of a variety of renal disorders. Genetic findings are increasingly used to inform the clinical management of many nephropathies, enabling targeted disease surveillance, choice of therapy, and family counselling. Genetic analysis has excellent diagnostic utility in paediatric nephrology, as illustrated by sequencing studies of patients with congenital anomalies of the kidney and urinary tract and steroid-resistant nephrotic syndrome. Although additional investigation is needed, pilot studies suggest that genetic testing can also provide similar diagnostic insight among adult patients. Reaching a genetic diagnosis first involves choosing the appropriate testing modality, as guided by the clinical presentation of the patient and the number of potential genes associated with the suspected nephropathy. Genome-wide sequencing increases diagnostic sensitivity relative to targeted panels, but holds the challenges of identifying causal variants in the vast amount of data generated and interpreting secondary findings. In order to realize the promise of genomic medicine for kidney disease, many technical, logistical, and ethical questions that accompany the implementation of genetic testing in nephrology must be addressed. The creation of evidence-based guidelines for the utilization and implementation of genetic testing in nephrology will help to translate genetic knowledge into improved clinical outcomes for patients with kidney disease.

Although individual inherited kidney diseases are rare, together they account for approximately 10% of adult end-stage renal disease (ESRD)[1–3] and at least 70% of paediatric[4,5] nephropathy. In addition to known hereditary aetiologies, compelling evidence exists for a genetic contribution across different forms of kidney disease. The `heritability` of glomerular filtration rate is estimated to be ~30–60% in the general population[6,7], and other parameters such as tubular transport of electrolytes similarly show substantial hereditability[8–10]. Moreover, 10–29% of adult patients with ESRD report a positive family history across different ethnicities and aetiologies[11– 13]. Prognosis, disease course, and appropriate management can differ markedly between hereditary and acquired forms of kidney disease, but these forms can be indistinguishable when traditional

diagnostics alone are used[14,15]. Moreover, as early-stage disease is often clinically silent, patients might not present until they reach ESRD. Owing to such late referral and the limitations of noninvasive diagnostic tools, the cause of kidney failure is classified as unknown in more than one in ten patients with ESRD[16–18]. Thus, earlier and more specific diagnoses are needed to enable delivery of effective care[19,20].

Technologies such as `chromosomal microarray` (CMA) and `next-generation sequencing` (NGS) were first introduced as research tools in the past decade and have empowered investigation of genetic contributions to disease through assessing variation across the `genome`[21–23]. These technologies are being increasingly deployed in the clinic, reflecting a shift in the work-up of suspected hereditary disorders in clinical medicine. Traditionally, diagnosis of individuals suspected to have an inherited form of nephropathy involved multiple clinical visits and complex and/or invasive studies (such as renal biopsy or biochemical testing) to identify the most likely aetiology, which the clinician would use to select one or a few associated genes for `genetic testing`. Now, a shift towards `genomic medicine` is occurring, wherein genome-wide testing approaches are used to identify the causal aetiology of disease in a patient, and the genetic variant or variants that are identified are used to guide their clinical care[24]. As sequencing costs are rapidly declining, genome-wide testing has been advocated as a sensitive and ultimately cost-effective first-line diagnostic test[25–27]. Use of such testing could help to surmount the diagnostic challenges posed by the substantial genetic and phenotypic heterogeneity[28] of many hereditary nephropathies.

However, in order to realize the promise of genomic medicine in nephrology, many complex questions must be answered, including how to identify patients for whom genetic testing is indicated, choose the appropriate test, identify causal variants, and translate genetic findings into personalized care. Addressing these questions requires thorough investigation in large patient cohorts of diverse ages, ethnicities, and disease aetiologies. The ethical, legal, and social implications (ELSIs) that accompany genetic testing on an increasingly broad scale must also be a priority.

In this Review, we examine the opportunities and challenges that accompany the shift to genomic medicine for the diagnosis of genetic diseases of the kidney and urinary tract. We discuss the tests that are available for the work-up of suspected hereditary nephropathy and their diagnostic advantages and limitations, the patient populations for whom genetic testing is indicated, the current guidelines for interpretation of sequence data to achieve a molecular diagnosis, and the value of a `genetic diagnosis` in nephrology. We highlight the key issues that must be addressed to enable implementation of genetic findings in nephrology clinical practice and discuss how they might be surmounted.

Diagnostic genetic testing

Diagnostic genetic testing aims to identify the mutation that is causal for disease in an individual patient, but the wealth of variation within the human genome makes this task difficult. The typical human genome contains approximately 3 billion DNA nucleotides, of which ~20 million may be altered without major consequences for an individual's health[29],

Author Manuscript

Author Manuscript

Author Manuscript

Author Manuscript

and ~20,000 genes, of which nearly 4,000 have been implicated in human disease[30]. Sequence changes might occur at any of the nucleotide sites and include `single-nucleotide variants` (SNVs), small `insertions or deletions` involving <5–10 bp (indels), and `structural variants`. Given the abundance of rare, predicted damaging variants in a typical human genome, the risk of falsely attributing causality is high[31]. Thus, a major challenge in genetic diagnostics is to identify which variants are disease-causing mutations. Common modalities for diagnostic genetic testing include `Sanger sequencing`, CMA, and NGS approaches, including `targeted next-generation sequencing panels`, `whole-exome sequencing` (WES) and `whole-genome sequencing` (WGS) (TABLE 1).

Sanger sequencing

Sanger sequencing has high analytical validity in detecting causal SNVs and small (<5–10 bp) insertions or deletions. Thus, this modality remains the gold standard for molecular diagnosis when a single-gene disorder is suspected and for confirmation of NGS findings[32,33]. Sanger sequencing also has utility for genomic regions refractory to NGS, such as those that are highly repetitive, homologous, or guanine–cytosine (GC)-rich. However, as Sanger sequencing is limited to single DNA fragments of <1,000 bp (REF. 34), this modality cannot detect larger structural variants and becomes increasingly costly and time-inefficient as the number of candidate genes increases, limiting its utility for genetically heterogeneous conditions[32,35].

Chromosomal microarray

Historically, testing for genomic disorders — that is, genetic diseases caused by structural variants[36] — involved `karyotyping`, which can detect chromosomal disorders, translocations, and other large genomic imbalances. However, many genomic disorders are caused by `copy number variants` (CNVs) that fall below the 1–2 Mb resolution of karyotyping[37]. CMA enables detection of both small and large CNVs[38,39].

Two major types of CMA are used in the clinical setting: `array comparative genomic hybridization` and `single-nucleotide polymorphism arrays`. Both of these techniques offer excellent genome-wide coverage and use enrichment of probes in clinically relevant regions to enable resolution at the single-exon level[23,40,41]. Owing to this high resolution, CMAs have as much as 10-fold increased diagnostic yield versus karyotyping for intellectual disability, autism, and multiple congenital anomalies[23,42,43] and are now recommended as a first-line diagnostic for these indications[23,44]. Unlike karyotyping, however, CMAs cannot detect `balanced chromosomal rearrangements` or low-grade mosaicism and have limited sensitivity to detect changes in certain regions, such as pseudogenes and repetitive elements. In addition, CMAs can generally resolve the boundaries of a CNV to only ~1–2 kb, hindering accurate determination of its size and of the genes affected[45,46], which are key criteria in diagnostic CNV interpretation[21,45]. Thus, findings need to be interpreted in the context of the coverage of the specific CMA platform utilized and the strength of clinical suspicion for a genomic disorder[44].

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

Applications

Congenital anomalies of the kidney and urinary tract (CAKUT) are the leading cause of paediatric nephropathy[5,47] and can present in isolation or as part of a multiorgan syndrome[48]. CMA has been shown to be an effective first-line diagnostic tool among patients with syndromic CAKUT[49,50] and may also have utility for those with nonsyndromic forms. For example, a study of 522 children with renal hypodysplasia identified CNVs that were pathogenic for a known genomic disorder in 55 of 380 (14.5%) patients with isolated genitourinary anomalies[50]. Among all studies published to date, pathogenic CNVs were identified in ~4–10% of patients with CAKUT and appear to be enriched among patients with renal parenchymal defects, explaining up to 10% of these cases[50,51–56]. These studies identified more than 40 distinct genomic disorders in children with kidney disease, with recurrent syndromes including deletions at the 17q12 (Online Mendelian Inheritance in Man (OMIM) 614527), 22q11.2 (OMIM 188400), and 16p11.2 (OMIM 611913) loci. Moreover, CMA analysis of a cohort of 419 children with all-cause chronic kidney disease (CKD) detected diagnostic CNVs in 7.4% of patients[55], a diagnostic yield comparable to that noted for the established indications of developmental delay or prenatal testing[23,43,51]. Importantly, the majority of patients studied were referred for routine evaluation to paediatric nephrology or urology clinics and had not been previously diagnosed with a syndromic form of disease, highlighting the difficulty of detecting genetic syndromes by use of traditional clinical methods.

In many cases, a diagnosis of a genomic disorder reclassifies a patient's disease, with important implications for subsequent clinical management. Moreover, these disorders often have pleiotropic effects, including metabolic, skeletal, and neurological complications, which may initiate unnecessary and prolonged work-up in the absence of a unifying aetiology. Alternately, such manifestations may be erroneously attributed as being secondary to renal dysfunction, leading to unachievable expectations for remission after appropriate nephrological treatment. For example, children with nephropathy are at increased risk of adverse neurocognitive outcomes, but this risk has been attributed to the medical and psychosocial burden of kidney disease[57–59]. However, a study of children with CKD demonstrated that those with a genomic disorder had poorer neurocognitive performance, independent of the severity of kidney disease[60]. These findings suggest that in some patients, neurocognitive deficits result from a genomic disorder that impairs both renal and neuropsychiatric function. Thus, CMA has the potential to explain seemingly disparate clinical features, to frame therapeutic expectations, and to guide treatment approaches. Although further investigation is needed to comprehensively ascertain the prevalence of genomic disorders and indications for CMA among adult patients with kidney disease, the above findings in children strongly support its utility as a first-line tool in the diagnostic evaluation of paediatric nephropathy.

Next-generation sequencing

NGS utilizes targeted capture and massively parallel sequencing to simultaneously assess variation in selected regions of the genome, enabling rapid and cost-effective large-scale genetic investigation[32,34,61,62]. Selected regions can be multiple genes of interest

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

(investigated using targeted NGS panels), all protein-coding regions (investigated using WES), or both coding and non-coding regions (investigated using WGS). Each NGS approach has merits and drawbacks in the current landscape of clinical testing, and selection of the optimal modality is rapidly evolving, reflecting technical capacity, cost-effectiveness, and knowledge of the individual patient and disease. As the technical expenses of sequencing have steadily decreased, the substantial time and monetary costs required for diagnostic interpretation have become the major barriers to systematic implementation in clinical practice[32,63].

Targeted panels

NGS gene panels use targeted enrichment of selected genes to provide rapid and inexpensive sequencing at higher coverage than that achieved with WES or WGS[33,35]. Such panels have been advocated as a first-line test for the molecular diagnosis of inherited nephropathies[4]. In this approach, patients are tested for a set of genes that are commonly associated with the phenotype under consideration; for example, a patient with nephrotic syndrome would be tested using a panel containing genes that are commonly implicated in hereditary forms of this disorder[4].

As NGS panels are quickly becoming a first-line diagnostic test, it is critical that they can accurately detect whether a particular genetic variant is present in the region of interest[64,65]. Organizations such as the American College of Medical Genetics and Genomics (ACMG)[66], British Association for Clinical Genetic Science (ACGS)[67], and European Society of Human Genetics (ESHG)[68] have published technical guidelines for clinical NGS regarding `sequencing coverage and depth` as well as other quality metrics. As certain regions, such as those with high GC content (for example, the first exon of *COL4A3*, which is associated with Alport syndrome (OMIM 104200; 203780) and thin basement membrane disease (OMIM 141200)) and those with high sequence homology (for example, the *PKD1* gene, which is associated with autosomal dominant polycystic kidney disease (OMIM 173900)), are poorly covered by NGS alone, laboratories often incorporate other methods such as Sanger sequencing and long-range PCR to ensure that all targeted regions are comprehensively covered at sufficient depth[33].

As sequencing is selective, targeted panels will not yield incidental findings in genes unrelated to the primary indication for testing, reducing the potential burden of `secondary findings` that would initiate additional clinical testing for patients and physicians. If the targeted panel testing is negative, the clinician can select another panel with broader content or proceed directly to WES or WGS. This sequential procedure may be the most comprehensive and cost-effective approach at present, particularly among patients whose presentation is strongly suggestive of a specific category of genetic disease[33,35,69].

Applications—Targeted gene panels are a sensitive and cost-effective diagnostic for a wide range of kidney disorders, including nephrotic syndrome[70,71], nephrolithiasis[72,73], nephronophthisis-related ciliopathies (NPHP-RC)[74,75], and CAKUT[76,77], albeit with variable disease-specific yield in the context of testing familial and/or paediatric cases. Such targeted testing is particularly well suited to diseases that have fairly low genetic

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

heterogeneity. For example, mutations in three genes, *COL4A3, COL4A4*, and *COL4A5*, cause Alport syndrome (OMIM 104200; 203780; 301050) and the related milder form, thin basement membrane disease (OMIM 141200)[78,79]. Targeted NGS sequencing of these genes detected causal variants in 84 (83%) of 101 patients with a clinical diagnosis of familial haematuria[80]. Supplementation with `multiplex ligation-dependent probe amplification`, CMA, and Sanger sequencing enabled identification of large genetic rearrangements and causal variants in regions that were not well captured by NGS alone.

However, many kidney diseases are genetically heterogeneous, and many nephropathy-associated genes can show clinically disparate presentations, reflecting both genetic and environmental modifiers[28]. In such cases, designing a gene panel that appropriately balances sensitivity and specificity is challenging. Restricting the number of genes in the panel reduces the cost and time needed for testing; however, the panel might require frequent updates as new genes are discovered and previously implicated genes are shown to have weaker disease associations than first reported. Assessing a greater number of genes increases diagnostic sensitivity but can also increase the detection rate of `variants of uncertain significance` (VUS), complicating interpretation and clinical follow-up. For example, targeted sequencing of 23 known genes associated with autosomal forms of CAKUT had an ~8% diagnostic yield: 6% in 17 genes for autosomal dominant forms[76] and 2.5% in 6 genes for autosomal recessive forms[77]. An expanded sequencing panel of 208 genes associated with syndromic or isolated CAKUT, including genes implicated by functional data, identified candidate variants in 151 of 453 (33%) patients as well as 32 VUS in 69 (15%) patients[81]. Further expansion to a 330-gene panel screen detected candidate variants in 122 of 204 (60%) patients with CAKUT but also identified 120 VUS in 89 patients (44%)[82].

For patients with more ambiguous presentations, ‘Mendeliome’ panels, which target all known disease-associated genes, have been suggested as a time and cost-effective first-line test, and the studies to date report high diagnostic yield across a range of clinical indications[83–85]. Such panels also enable detection of `phenotypic expansions` of known genetic diseases but require periodic updates to include newly discovered disease-associated genes. Thus, the diagnostic utility and cost-effectiveness of Mendeliome panels relative to WES and WGS merits further in-depth study.

Whole-exome and whole-genome sequencing

WES and WGS provide more comprehensive testing than targeted NGS panels because they assess variation across the genome. These unbiased approaches have many advantages, including increased sensitivity for diagnosis of disorders with high genetic and/or phenotypic heterogeneity and the ability to achieve a specific diagnosis when traditional clinical methods are unsuccessful. WES and WGS also enable reanalysis of sequence data, which may include recalling variants from raw data, reannotating called variants by use of novel bioinformatics tools, and/or re-examining annotated variants in light of newly discovered gene–disease associations. Various analytical frameworks can also be used to identify novel candidate genes for follow-up study[31,86,87], and such re-examination can lead to additional diagnoses, increasing overall diagnostic yield[88–91].

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

Per-base coverage is generally lower with WES and WGS than with targeted panels. However, an *in silico* analysis showed that WES with standard coverage (≥10 times coverage of 90% of bases) was adequate to identify 98.6% of sites previously found to have pathogenic variants by targeted panel[92], suggesting that the sensitivity of WES is sufficient for diagnostic sequencing in most cases. Nevertheless, clinically relevant segments of the genome can be missed when using WES alone[93]. For example, the sites corresponding to ~50% of reported pathogenic variants in the *WT1* gene, which is associated with hereditary nephrotic syndrome (OMIM 256370) and Deny–Drash syndrome (OMIM 194080), were poorly covered across three leading WES capture kits[94]. Further development of sequencing technology will help to increase technical accuracy, achieve more uniform coverage, and decrease costs[61,62]. Thus, increasingly comprehensive genomic sequencing has been predicted to define the future of clinical genetic testing, with targeted panels superseded by WES, which in turn will be overtaken by WGS as a first-line diagnostic[32,35,63].

Whether WES or WGS will prove to be a superior clinical diagnostic tool in the near future is a topic of ongoing debate. As known causal variants for Mendelian disorders overwhelmingly lie in coding regions[95,96], WES has been suggested as a time-efficient and cost-efficient means for clinical diagnosis and genetic discovery[86,97,98] and has been successfully used for a variety of clinical indications. To date, the majority of diagnostic variants identified in clinical WGS investigations have been found in exonic regions[99–102]. Non-coding variants have, however, been implicated in various kidney disorders[103–107]. For example, WGS detected a deep intronic mutation in *DGKE* in two unrelated families with infantile-onset atypical haemolytic uraemic syndrome (OMIM 615008) who had been left undiagnosed by use of WES[103]. Subsequent analysis of patient RNA showed that the variant created a novel splice site that abrogated normal protein function. Intronic mutations resulting in altered splicing have likewise been noted in genetically unresolved cases of Alport syndrome[104], Schimke immune-osseous dysplasia[105] (OMIM 242900), and Gitelman syndrome[106] (OMIM 263800). Sequencing the whole genome also avoids capture bias and provides more complete per-base coverage of coding and non-coding regions[108,109], facilitating accurate detection of variants in genes with highly homologous regions, such as *PKD1* (REF. 110), and of structural variants, such as those found in several patients with Joubert syndrome[111]. Although further study is needed, WGS has been reported to detect causal variants in ~20–40% of patients left undiagnosed by WES and/or CMA[112–114].

Importantly, some types of variants remain wholly refractory to detection using current NGS technologies. For example, causal variants in the *MUC1* gene, which is associated with autosomal dominant tubulointerstitial kidney disease (ADTKD-*MUC1*; OMIM 174000) and contains a highly repetitive, GC-rich sequence, were missed by NGS-based regional capture, WES, and WGS and were identified only by long-range PCR and molecular cloning[115]. A novel assay based on mass spectrometry has been recently developed for diagnosis of ADTKD-*MUC1* (REF. 116), and with the advent of long-read sequencing, NGS-based detection of such regions may become feasible[61].

Given such increased diagnostic and analytical sensitivity, WGS has the potential to provide a single-test solution. However, with higher-performance WES capture platforms and improvements in NGS technology, the extent to which the benefits of the expanded search

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

space outweigh the burdens of sequencing costs, data storage, and clinical interpretation and follow-up remains unclear[117,118].

To date, investigations of the diagnostic yield of genome-wide testing in nephrology have overwhelmingly used WES. To our knowledge, the efficacy of WGS in this field remains to be comprehensively assessed. Thus, we focus below on selected studies demonstrating the utility of WES as a diagnostic tool for various forms of nephropathy.

Testing in an expanding genetic spectrum—WES has been successfully employed for a variety of conditions with high genetic heterogeneity, such as NPHP-RC and nephrotic syndrome. NPHP-RC has >90 known causal genes[119], and the advent of NGS has accelerated the discovery of additional causal genes[120]. Expansion of the genetic search space thus enables identification of mutations in noncanonical genes, increasing diagnostic yield relative to targeted panel testing. Detection rates in testing for NPHP-RC were 12% with a 13-gene panel[121], 21% with a 34-gene panel[74], and ~60–70% with WES[122,123]. Similarly, WES identified causal variants in 49 of 187 (26.2%) paediatric patients with steroid-resistant nephrotic syndrome (SRNS)[124]. Although 30 (61.2%) of the 49 patients with resolved cases had mutations in canonical genes for early-onset SRNS (*NPHS1, NPHS2*, or *WT1*), three had diagnostic variants in genes classically associated with other renal disorders, including *DGKE* (membranoproliferative glomerulonephritis and/or atypical haemolytic uraemic syndrome; OMIM 615008), *COL4A3* (Alport syndrome), and *OCRL* (Dent disease 2; OMIM 300555). These three patients all presented with primary SRNS and focal segmental glomerulosclerosis (FSGS) on renal biopsy, suggesting that the findings did not result from initial clinical misphenotyping.

Moreover, use of NGS has led to the detection of novel genes in many disorders that were previously thought to be highly genetically homogenous. For example, polycystic kidney disease (PKD) was long thought to result from mutations in only three genes, with those in *PKD1* and *PKD2* accounting for the autosomal dominant form (ADPKD; OMIM 173900, 613095) and those in *PKHD1* leading to autosomal recessive disease (ARPKD; OMIM 263200). However, ~7–10% of families with ADPKD lack mutations in *PKD1* or *PKD2* (REFS 125,126), and *PKHD1* mutations are not detected in at least 13% of patients with ARPKD[127,128]. WES of mutation-negative families implicated *GANAB* in ADPKD[129] and *DZIP1L* in ARPKD[130], broadening the genetic spectrum of PKD.

Expanding the phenotypic spectrum—Conversely, WES has demonstrated that many genetic disorders can produce a wider range of phenotypes than previously thought. These phenotypic expansions dispel the classical view that a one-to-one relationship exists between a gene and a disease and challenge traditional clinical classifications[28]. For example, mutations in *COL4A3, COL4A4*, and *COL4A5*, which are associated with Alport syndrome, have been detected among patients with a clinical diagnosis of nephrotic syndrome, expanding the range of phenotypes associated with *COL4A*-mediated nephropathy[131,132]. The variability of phenotypes among patients with mutations in *HNF1B* similarly exemplifies this point. Although *HNF1B* mutations are classically associated with renal cysts and diabetes syndrome (OMIM 137920), patients with these mutations can be nondiabetic or have other, noncystic forms of renal disease[133,134]. For example, patients

Author Manuscript

with *HNF1B*-mediated disease can present with hyperuricaemia and glomerulocystic kidney disease, such that they may be mistakenly diagnosed with ADTKD; others may present with hypomagnesaemia and hypocalciuria, causing an assumption that they have Gitelman syndrome[133]. Moreover, many of the extrarenal features of *HNF1B*-mediated disease, such as hyperuricaemia and hyperparathyroidism, can also occur as secondary complications of renal dysfunction; thus, patients might not be suspected to have a genetic form of nephropathy, especially those who are older and/or have no family history[133].

Other examples include the expansion of variants in *PAX2*, which are classically associated with CAKUT (OMIM 120330), to include hereditary FSGS (OMIM 616002)[135] and of biallelic mutations in *TTC21B* to span both cystic and glomerular disease[136,137]. Similarly, the phenotypic spectrum of *UMOD*-associated kidney disease (OMIM 609886; 162000; 603860) encompasses both tubulointerstitial nephritis and glomerulocystic disease[138], and the presentation of patients with *CLCN5* mutations, causal for Dent disease 1 (OMIM 300009), may range from tubulointerstitial disease with electrolyte imbalances[139,140] to nephrotic-range proteinuria and glomerulosclerosis on renal biopsy[141,142].

Proteinuria and glomerulosclerosis have also been reported among patients with variants in *SLC12A3*, which are associated with Gitelman syndrome, a salt-wasting distal tubulopathy (OMIM 263800)[143–145]. Similarly, mutations in *PARN* cause a telomere syndrome traditionally associated with pulmonary fibrosis and bone marrow failure (OMIM 616371), but a WES study suggests that some patients with these mutations initially present with renal tubulointerstitial fibrosis, expanding the phenotypic spectrum of *PARN*-mediated disease[146].

Resolving undiagnosed disorders—WES has transformed paediatric and neonatal care by providing a means to rapidly resolve undiagnosed cases, informing prognosis and clinical management[22,101,147]. Similarly, WES may have considerable diagnostic value for patients who present with nonspecific renal phenotypes or kidney disease of unknown aetiology (REFS 148–151). For example, one of the first clinical applications of WES was for a neonate who presented with hypokalaemic metabolic alkalosis and was thus suspected to have Bartter syndrome[148]. WES identified no candidate variants at Bartter-associated loci but rather a homozygous substitution mutation at a highly conserved residue in *SLC26A3*, and clinical follow-up confirmed the genetic diagnosis of congenital chloride diarrhoea (OMIM 214700). Putatively pathogenic variants in *SLC26A3* were found in an additional 5 of 39 (13%) patients with presumed Bartter syndrome, supporting the utility of exome-wide analysis in resolving such clinically inscrutable cases.

Subsequent studies have further highlighted this utility. For example, exome analysis of 79 children who presented with increased renal echogenicity on ultrasonography identified causal variants in 63% of these patients[122]. Notably, 36% of the patients with a genetic diagnosis were found to have a disorder other than NPHP-RC, which was the diagnosis suspected on the basis of the ultrasonography results. The researchers hypothesized that the misclassification of patients reflects the nonspecificity of increased renal echogenicity for diagnosis of NPHP-RC. Similarly, WES of 33 consanguineous families diagnosed with CAKUT detected pathogenic variants in 9 (27%) families; notably, 4 (44%) of these families had mutations in genes unassociated with CAKUT, and on clinical follow-up, they were

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

found to have phenotypes concordant with these alternate genetic aetiologies of disease[152]. In many patients, these unexpected diagnoses had important implications for management and therapy, including tight regulation of salt and water intake for nephrogenic diabetes insipidus type 2 (OMIM 125800)[153], cysteamine supplementation for nephropathic cystinosis (OMIM 219800)[154], and combined liver and renal transplantation for primary hyperoxaluria type 1 (OMIM 259900)[155].

Moreover, a pilot study of WES in adults with familial or undiagnosed nephropathy identified diagnostic findings in 22 of 92 (24%) patients[146]. Diagnostic yield was notably high among those with kidney disease of unknown aetiology, with 9 of 16 (56%) patients being diagnosed. These diagnoses encompassed a variety of genetic nephropathies, including autosomal and X-linked forms of Alport syndrome, Dent disease, CHARGE syndrome (OMIM 214800), and *HNF1B*-associated disease. In addition to ending the ‘diagnostic odyssey’, the genetic diagnoses resulting from WES impacted clinical care in many patients, including guiding choice of therapy (for example, steroid avoidance in patients with glomerulonephritis and *COL4A3–5* mutations), advising subsequent work-up and surveillance of associated extrarenal comorbidities (for example, screening for diabetes and liver function in a patient with an *HNF1B* mutation), and informing transplant prognosis and choice of donor (for example, a low risk of disease recurrence and genetic screening for candidate living related donors in a patient with Dent disease). These findings support the diagnostic utility of WES for patients with kidney disease of unknown aetiology, particularly those with familial or early-onset disease, and highlight the need for further research in this field in larger cohorts.

Indications for genetic work-up

With the widening availability and declining costs of sequencing technologies, nephrologists will increasingly incorporate clinical genetic testing into their diagnostic armamentarium. There is a risk that these new technologies will be adopted prematurely, before systematic evidence of their utility has been generated. Hence, there is a need for large, multicentre studies of diverse cohorts to develop evidence-based guidelines regarding the indications and utility of genetic testing in nephrology.

Currently, genetic testing is recommended as part of the diagnostic work-up for patients with paediatric kidney disease, especially among those with nondiagnostic presentations[156]. For adult patients, genetic testing is suggested only for those who are strongly suspected to have a known hereditary form of nephropathy. Other indications for genetic work-up include phenotypes that have a strong hereditary basis, such as CAKUT, for which CMA seems to be a valuable first-line diagnostic modality in addition to NGS-based approaches. Certain clinical situations might also merit genetic testing, such as those in which diagnostic findings would enable patients to avoid undergoing unnecessary invasive procedures (for example, renal biopsy in patients with nephronophthisis) or prevent them from receiving ineffective and costly treatment with substantial adverse effects (for example, steroid therapy in patients with hereditary aetiologies of SRNS). Genetic testing is also advised for females with clinical features and/or a history suggestive of a monogenic X-linked nephropathy, such as X-linked Alport syndrome (OMIM 301050) or Fabry disease (OMIM 301500), because

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

although female carriers of these diseases generally display a milder (often subclinical) phenotype than is seen in males, they can develop severe disease[157–159]. At present, clinicians are generally advised to start with a disease-specific genetic panel and if the results are negative, to proceed to a Mendeliome panel, WES, or WGS[35,66,68].

Genetic testing has also been recommended in the evaluation of potential living kidney donors, with donation contraindicated among those found to have autosomal dominant forms of inherited kidney disease such as ADPKD (OMIM 173900, 613095, 600666) or to share genetic susceptibility factors for atypical haemolytic uraemic syndrome[160]. In such cases, positive findings not only guide choice of donor but also might inform renal prognosis; for example, among patients with ADPKD owing to mutations in *PKD1* (OMIM 173900), those with loss-of-function mutations have more severe disease and progress faster to ESRD than those with missense mutations[161,162]. Carriers of autosomal recessive disorders have generally been deemed suitable kidney donors, as individuals who are heterozygous for a recessive causal `allele` are not expected to develop the disease[160]. However, reports of milder, subclinical disease phenotypes among carriers suggest that these individuals are at higher risk of developing nephropathy than previously thought and therefore may warrant nephrological surveillance. For example, hepatorenal involvement (renal echogenicity and/or liver cysts) has been noted in obligate heterozygote parents of patients with ARPKD (OMIM 263200)[163], and mild renal acidification defects and nephrolithiasis have been observed in individuals who are heterozygous for mutations in *ATP6V1B1*, which are associated with distal renal tubular acidosis with deafness (OMIM 267300)[164]. Thus, additional study is needed to assess the long-term implications of carrier status for renal function, risk of developing kidney disease, and outcomes following kidney donation.

The available epidemiological and genetic studies support the use of genetic testing in nephropathies of unknown aetiology, particularly in the setting of a compelling family history of early-onset renal failure. The 2017 US Renal Data System report notes that in ~14% of adult and ~19% of paediatric patients with incident ESRD[18], the clinical diagnosis is “other” or “unknown”, and the European Renal Association–European Dialysis and Transplant Association[17] and Australia and New Zealand Dialysis and Transplant[16] registries report similar statistics. As renal biopsy is generally contraindicated in ESRD, genetic testing is a promising diagnostic tool, and case reports demonstrate the utility of genetic findings in this patient population[165–168]. For example, in a 12-year-old boy presumed to have nonsyndromic infantile-onset retinal dystrophy, identification of Senior–Loken syndrome 5 (OMIM 609254) led to early diagnosis of unrecognized CKD, enabling preplanned initiation of dialysis, appropriate donor selection for renal transplantation, and surveillance of at-risk family members[167]. Similarly, detection of *INF2*-mediated focal segmental glomerulosclerosis (OMIM 613237)[166] and *LMX1B* glomerulopathy (OMIM 161200)[165] in patients with familial ESRD of unknown origin helped to inform transplant prognosis and choice of donor, as these diagnoses are associated with low risk of disease recurrence and indicate genetic screening for candidate living related donors. Genetic diagnosis can also lead to targeted therapy and improved post-transplantation outcomes. For example, genetic testing of a 67-year-old woman with ESRD of unknown aetiology revealed adenine phosphoribosyltransferase (APRT) deficiency (OMIM 614723)[168]; the resulting initiation of xanthine dehydrogenase inhibitor therapy (allopurinol) prevented recurrence of crystalline nephropathy and allograft loss in this patient. Given the notable prevalence of kidney disease of unknown aetiology, even a modest diagnostic yield from genetic testing could have a large impact on clinical care.

The value of a genetic diagnosis

In addition to pinpointing the cause of disease, genetic diagnosis can inform clinical prognosis and guide patient management (TABLE 2). In general, patients and their physicians want a clear understanding of their disease, why it occurred, and how it will affect their health and medical care as well as that of their families[169]. As distinct pathophysiological processes can result in indistinguishable clinical presentations, the precise aetiology can remain unclear despite extensive history-taking and biochemical, imaging, and histopathological studies. This 'diagnostic odyssey' has substantial time, financial, and psychosocial costs for patients and their families and is a substantial burden on the health-care system. Thus, in addition to helping guide subsequent care, a genetic diagnosis holds substantial value through ending this process[27,69,170,171].

Importantly, translating genetic findings into improved patient care requires longitudinal studies of large cohorts of individuals with genetic diagnoses. Long-term follow-up of patients undergoing sequencing is needed to study the impact of genetic information on clinical management, health-care utilization, and outcomes. Rare disease referral networks, such as the European Reference Network for Rare Kidney Diseases[172,173], the National Institute of Health Rare Diseases Clinical Research Network[174], and the United Kingdom Kidney Research Consortium[175], will help to achieve this aim. Moreover, the knowledge generated will enable the development of best practice guidelines regarding diagnostic work-up and treatment of rare hereditary renal disorders. A genetic diagnosis can also enable referral for targeted clinical trials of therapies that might provide benefit in specific patient populations, such as microRNA inhibition for Alport syndrome[176] (OMIM 104200, 203780, 301050) and small-interfering-RNA blockade for primary hyperoxaluria type 1[177] (OMIM 259900). Disease-specific support groups can also help to direct patients to trials and other relevant clinical resources[178–180] and serve as key sources of psychosocial support for affected individuals and their families.

Finally, genetic-based stratification of clinical trials has the potential to prevent exposure to unnecessary risk of patients who are unlikely to benefit from an intervention while reducing confounders that may mask its benefit. For example, genetic testing could be used to exclude patients with hereditary forms of nephrotic syndrome, who do not tend to respond to steroid therapy[181], from a trial investigating the efficacy of a novel corticosteroid agent.

Clinical sequence interpretation

The aim of clinical sequence interpretation is to identify the genetic variant that is responsible for the phenotype of an individual patient. As the identified variant is used to guide subsequent care, it is critical that clinical sequence interpretation be highly accurate and reproducible[182]. However, the abundance of sequence variation in a typical human

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

genome and the vast search space provided by genome-wide testing results in a high risk of falsely ascribing causality to benign variants[183]. Although established guidelines for diagnostic interpretation exist[67,68,182], the process often remains time-consuming and highly subjective, requiring expert judgement at each step. A variety of online resources are available to aid geneticists and clinicians as they navigate the process of diagnostic sequence interpretation and application of genetic findings into clinical care (TABLE 3).

Diagnostic analysis is guided by the phenotype of the patient. Ordering clinicians are thus instructed to provide accurate and complete clinical information[182]; however, no standards currently exist for what information should be provided and/or who is qualified to give this information[184]. Moreover, even ostensibly specific clinical diagnoses may comprise a wide array of genetic and acquired disorders. For example, a diagnosis of primary FSGS could result from mutations in any one of >50 genes[124]; without further clinical information, such as age of onset, presence of extrarenal features, or pattern of inheritance, a geneticist would be hard-pressed to prioritize candidate variants during subsequent sequence interpretation. Referring clinicians should, therefore, provide detailed clinical information to the diagnostic laboratory and be prepared to discuss the patient in greater detail with the molecular geneticist in charge of sequence interpretation.

The first step in clinical sequence interpretation is to select the genes in which mutations can result in a phenotype compatible with the clinical presentation of the patient (FIG. 1). Attempts have been made to catalogue the genes that are associated with hereditary forms of nephropathy and classify them by their associated broad phenotype[1,4,185], but no systematic procedures or consensus guidelines exist regarding which genes should be evaluated for a given category of kidney disease. The choice is becoming increasingly complex owing to phenotypic expansions and is complicated because genes that are traditionally associated with nonrenal disorders can also present with nephropathy[186–188]. For example, mutations in *HNF4A* are classically implicated in maturity-onset diabetes of the young type 1 (MODY1; OMIM 125850) without renal involvement; however, the p.R76W `missense variant` has been noted in patients presenting with both Fanconi proximal tubular syndrome and MODY1 (REFS 186,187). Similarly, the identification of mutations in *FOXP1* in patients with CAKUT suggest that the phenotypic spectrum of these mutations encompasses CAKUT as well as intellectual disability (OMIM 613670)[188]. These situations require geneticists with domain expertise, who can recognize the causal connection between the mutation and the kidney phenotype. An additional challenge is the continuous need to assess the strength of gene–disease associations, as new genes continue to be rapidly identified[21] and additional research can cast doubt on those that have previously been implicated in a disease[189,190].

Interpretation at the variant level holds further complexity. Current guidelines evaluate a given variant in the context of the genetic architecture of the disease and the available literature. Lines of evidence include previous case reports, being in the same region and/or belonging to one of the functional types of variants previously noted as being causal for the disorder, having a population frequency compatible with that expected for the disease, and experimental and/or *in silico* support for a deleterious effect on protein function. Geneticists must examine the relevant observations for each of these criteria and combine them to arrive at an overall variant-level classification of pathogenic, likely pathogenic, likely benign, benign, or VUS[182].

Finally, the genetic findings must be assessed for concordance with the clinical presentation of the patient in addition to the genetic architecture of the disease. In some cases, this process is fairly straightforward; for example, as `haploinsufficiency` is recognized as the genetic mechanism of *HNF1B*-mediated disease[134] and *HNF1B* is highly intolerant of `loss-of-function variation`, a novel `nonsense variant` found in a patient with cystic renal disease and early-onset diabetes can be deemed likely causal. By contrast, a novel *HNF1B* missense variant, even if predicted to be deleterious based on multiple *in silico* algorithms, would require additional evidence to support pathogenicity. Additional work-up might involve parental testing to ascertain *de novo* status in sporadic cases, examining segregation if multiple affected family members are present, evaluating the patient for other features associated with the candidate diagnosis (for example, in the case of *HNF1B*-mediated disease, diabetes, gout, hypomagnesaemia, and genital abnormalities), and/or performing functional studies to model the effect of the variant on protein function. Such work-up is critical to clarify the clinical relevance of genetic findings, especially in the context of large multigene panels or genome-wide testing, where multiple candidate variants may be found[182,184,191]. Additional genetic and/or clinical testing can, however, involve substantial time and monetary costs[192] and, in some cases, might not be feasible (for example, blood relatives may be unavailable for genetic testing, preventing `variant phasing` or the determination of *de novo* status).

Population-wide `allele frequency` data have emerged as powerful first-line tools in clinical sequence interpretation[183]. The development of large public sequence databases has shed light on the spectrum of allele frequencies across populations of diverse ancestries[29,193] and has demonstrated that a large number of previously reported variants are unlikely to be pathogenic because they are present at frequencies exceeding the prevalence of the associated disease[193–196]. For example, in the Human Gene Mutation Database, the p.Ser487Leu variant in the *EYA1* gene is noted as causal for branchio-oto-renal syndrome (BOR; OMIM 113650) on the basis of two publications[197,198]. However, this variant has been reclassified by four independent diagnostic laboratories as a VUS or likely benign[199], and noted as a VUS in two publications[76,81], because of its high prevalence in the general population. The variant is present in 197 individuals in gnomAD (a large population control database), corresponding to a global frequency of 1 in 1,500, and is present in more than 1 in 1,000 Europeans. By contrast, BOR is estimated to have a prevalence of 1 in 40,000 and is thought to be fully penetrant[200]. With frequencies 28-fold and 50-fold higher than the total prevalence of BOR, the p.Ser487Leu variant is unlikely to be causal for such a rare, highly penetrant, autosomal dominant, monogenic disorder.

Thus, a great need exists for review of clinical variant databases using newly available population genetic data. In the meantime, variant interpretation will require time-intensive and subjective curation of the primary literature in the context of often limited knowledge of the prevalence, `penetrance`, and expressivity of a disease. In addition, many of the variants in clinical databases may have been classified by a single diagnostic laboratory; with no further explanation and/or supporting data, such findings have limited value.

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

Given the many layers of complexity, the existence of persistent interlaboratory and even inter-reviewer discordance in variant classification[201–204] despite adoption of fine-grained variant interpretation guidelines[182] is unsurprising. Frameworks for semiquantitative assessment of the clinical validity of gene–disease associations[205] and semiautomated clinical variant interpretation[206,207] have been proposed and might help to increase the reproducibility and efficiency of clinical sequence interpretation. However, these approaches still rely on subjective review of genetic and experimental evidence from the primary literature, and thus, the potential for divergent interpretation remains. Creation of consensus guidelines and quantitative standards will enable more objective and automated analysis at some steps, but as clinical sequence interpretation ultimately relies on clinical judgement, some degree of subjectivity will remain.

Applying genetic findings in the clinic

A genetic diagnosis provides a valuable answer but is only a starting point. For genetic findings to have clinical utility, they must be applied in the context of clinical care. This process is as complex as that of clinical sequence interpretation, and multiple barriers must be overcome to enable the promise of genomic medicine to be achieved. Key challenges in the implementation of genetic findings into clinical nephrology include return of results, physician education, sequence reanalysis, and the consideration of ELSIs[208–210].

Return of results

Clinical genetic testing is rapidly moving towards genome-wide assessment[32,35,63]. This expanded genetic scope increases diagnostic sensitivity but also has the potential to identify variants that are unrelated to the primary indication for testing. Such secondary findings must be considered with respect to their clinical validity and actionability[211]. Clinically valid findings include those that can be used to accurately predict that a patient will have the associated condition[212]; these encompass variants in genes for highly penetrant Mendelian diseases, pharmacogenomic variants that are informative regarding drug metabolism, and risk variants that affect susceptibility for a given condition. This category also includes clinically actionable variants, the detection of which would enable a physician to implement interventions that prevent or lessen the clinical consequences of the disease for which the variant confers increased risk. Clinically actionable variants have been recommended for return by both the ACMG[213,214] and the ESHG[215].

Currently, the ACMG advises returning known and expected pathogenic variants in 59 genes to patients regardless of their age or indication[214]. These genes encompass conditions deemed to be highly penetrant and actionable and predominantly consist of those that are associated with various hereditary forms of cancer and cardiovascular disease. Sequencing studies on large, unselected adult cohorts show that approximately 1–3% of the general population has a pathogenic mutation in one of these 59 genes[216,217]. Importantly, the ACMG actionable list includes genes that are associated with conditions relevant to renal medicine, such that the broadening use of genome sequencing may lead to additional nephrology consultations. These conditions include hereditary pheochromocytoma-paraganglioma syndrome (OMIM 168000, 601650, 605373, 115310), multiple endocrine

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

neoplasia (OMIM 131100, 171400, 162300), Wilms tumour (OMIM 194070), Fabry disease (OMIM 301500), Von Hippel–Landau syndrome (OMIM 193300), and tuberous sclerosis complex (OMIM 191100, 613254). Moreover, the detection of actionable mutations in other ACMG genes can impact nephrologic care, such as pretransplant defibrillator implantation in kidney transplant recipients with a *KCNQ1* mutation causal for long QT syndrome (OMIM 192500) or reduction of the dosage of immunosuppressive therapy in patients with mutations in genes that are associated with hereditary cancers, such *BRCA1*.

The ACMG encourages clinical specialists to nominate gene–disease pairs that they feel meet these actionability criteria as well as selected pharmacogenomic variants for medications that are commonly prescribed and/or associated with serious adverse events. Thus, there may be an opportunity to add nephrology-specific loci to the ACMG list, such as genes for highly penetrant and medically actionable hereditary nephropathies and pharmacogenomic variants that affect metabolism of medications commonly used in the care of patients with CKD[218,219]. Formation of multicentre interdisciplinary working groups and use of evidence-based frameworks to assess disease actionability[220] would greatly facilitate this effort.

Continuous review

As new genetic knowledge emerges, classifications shift. New genetic or experimental data may reclassify a mutation that was previously deemed diagnostic as a VUS or benign variant as pathogenic. Moreover, discovery of new genes may lead to a genetic diagnosis upon review of WES or WGS data from previously unsolved cases. As physicians use genetic diagnoses to guide care, such shifts are hugely important — altered classification of a variant can result in altered management of patients and their families. Yet no explicit standards for review of clinical genetic testing data currently exist, and the practice is rare, with a 2017 study reporting that only 1 of 21 laboratories surveyed routinely engaged in the practice[221].

In addition to questions regarding the optimal frequency and analytical methodology, continuous review of sequence data involves a multitude of ELSIs, including who should be responsible for requesting reanalysis, physician liability and duty to inform versus the right of patients not to know, and the psychosocial impact of recontact on patients and their families[222,223]. Given the scientific and ethical complexity and the many stake-holders involved, continuous review is not an easy issue to address or to create policies around; nevertheless, the issue is unavoidable as sequencing is increasingly incorporated into clinical practice. Comprehensive study of the clinical utility, cost-effectiveness, and psychosocial impact of continuous review and dialogue between relevant stakeholders, including patients, physicians, and genetics professionals, will help to ascertain its advantages and drawbacks and enable creation of formal guidelines regarding its implementation.

Genetic education and counselling

Under current guidelines for clinical genome-wide testing, the ordering clinician is expected to ensure informed consent by providing patients with comprehensive pretest counselling, including discussing the limitations of the test, the potential for secondary findings, and the complexity of the genetic interpretation[68,224]. The clinician is likewise expected to return

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

not only the primary results but also any secondary findings if the patient has opted to receive them. Investigations to date show that the majority of patients do opt to receive secondary findings[225], which necessitates a greater breadth and depth of genetics knowledge for the interpretation of their test results. However, there is currently a shortage of clinicians with adequate knowledge in genetics, genetic counsellors, and clinical geneticists who are capable of administering such comprehensive counselling[226,227]. Although genetics is being increasingly included in medical education, reports suggest that limited time and a lack of integration of genetics with clinical topics leaves students unprepared to apply genomics in patient care[228]. For example, a survey of recently graduated nephrology fellows noted that 65% felt that they had insufficient competence regarding genetic renal diseases, despite considering them important to their current clinical practice[229]. Among practising clinicians, no requirement currently exists for nongeneticists to have any specific knowledge or competencies in genetics[230], such that more senior clinicians may also feel unprepared.

Given the complexity of interpretation of genome-wide data and the many demands on their time, expecting nephrologists to act as genetic counsellors may be unreasonable. Rather, nephrologists should be expected to have a basic familiarity with genetics as well as more detailed knowledge of genetic forms of renal disease and to be aware of the general best practices regarding genetic testing. In the future, nephrogenetics may emerge as a superspecialty, similar to transplant or interventional nephrology. Genetic counsellors specialized in nephrology should become part of multidisciplinary teams fully integrated into the clinical setting, as has been successfully implemented in oncology[231] and cardiology[232]. In the absence of a geneticist in the clinical team, patients should be referred to genetic counsellors for counselling before and after testing. Efforts to provide genetics education to physicians, foster interaction between referring physicians and clinical testing laboratories, and create clinical decision support tools will help to achieve this aim and will facilitate implementation of clinical care based on genetic findings[233,234].

Ethical, legal, and social implications

The ELSI programme was founded as an integral part of the Human Genome Project with the understanding that genetic information can affect individuals, families, and society in a way that few other medical findings can. The historical role of human genetics in the development of eugenics and associated governmental policies such as compulsory sterilization invite caution as sequencing is introduced to general clinical practice. Here, we highlight some of the key ELSIs that must be considered when implementing genomic medicine in nephrology.

Participation in genetic research

In the landscape of genomic medicine, the boundaries between bench research and bedside care have become increasingly blurred. Participating in research can directly impact the clinical care and disease course of patients with hereditary nephropathies, for example, through enrolling in clinical trials such as the EARLY PRO-TECT trial, which is assessing the safety and efficacy of angiotensin-converting-enzyme inhibition in children with Alport syndrome[235,236]. In addition, researchers have begun to integrate patients' electronic health-

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

care records with their genetic data to study complex phenotypes such as resistant hypertension[237], and the promise of receiving medically actionable findings is a major incentive for many participants in genetic research[238,239].

The results generated through taking part in genetic studies differ markedly, however, from those that are returned from clinical diagnostic testing. A clinical genetic test aims to provide a genetic diagnosis for a patient within a defined time period, whereas sequencing performed in the context of genetic research aims to generate generalizable knowledge useful for future patients[240]. Although the latter approach might lead to diagnostic results, the time frame for their return is generally indefinite, and owing to the lack of regulation surrounding research-level genetic sequencing, putatively causal variants should be validated in a Clinical Laboratory Improvement Amendments (CLIA) certified laboratory before they can be returned in the context of clinical care[241,242]. Some have argued for the unification of research and clinical genetic testing, including requiring all research-level sequencing to be conducted in a CLIA laboratory environment to enable genetic discoveries to be rapidly implemented in patient care[243,244]. In the meantime, however, genetic counselling is needed to direct patients to the indicated sequencing modality given the clinical context (such as the urgency of a genetic diagnosis) and to ensure that they have appropriate expectations regarding what they may learn and in what time frame.

Minority populations

Substantial racial and ethnic disparities, which likely stem from both genetic and environmental factors, exist in kidney disease prevalence, severity, and treatment outcomes[245,246]. Importantly, knowledge of ancestry-specific alleles can have clinical utility for Mendelian nephropathies and for more common, complex forms of CKD. For example, founder mutations for autosomal recessive Alport syndrome (OMIM 203780)[247], Fanconi anaemia type C (OMIM 227645)[248], and Zellweger syndrome (OMIM 614866)[249] have been documented among Ashkenazi Jews, such that carrier screening may be beneficial in this population. With respect to more common, complex forms of CKD, the *APOL1* risk genotypes (BOX 1) substantially impact disease risk and clinical outcomes among patients of sub-Saharan African descent[250–252,287], and the sickle cell trait (*HBB* variant) may similarly confer increased CKD risk in this population[253,254].

Knowledge of population-specific allele frequencies can also help to prevent genetic misdiagnosis. Owing to a paucity of appropriate population controls, minority genomes have been frequently interpreted in the context of European sequence data, yielding an excess of reportedly pathogenic variants and VUS[255,256]. For example, in an analysis of genetic variants listed as pathogenic for hypertrophic cardiomyopathy, those with frequencies that were too high to be compatible with disease causality were significantly over-represented among healthy African Americans[256]. Importantly, these benign variants had been returned as diagnostic findings to African-American patients undergoing genetic testing for hypertrophic cardiomyopathy. Such false positive results can result in inaccurate understanding of risk status, medical mismanagement (for example, unnecessary implantation of a cardioverter–defibrillator), and substantial psychological distress for patients and their families. Thus, evaluation of sequence data in the context of a patient's

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

ancestry is critical to avert variant misinterpretation and the associated clinical perils. In addition, diverse population control databases are needed to address such disparities in genetic diagnostic testing among minority populations[257,258].

Genetic testing has been historically underutilized by minority populations, reflecting disparities in health-care access as well as negative perceptions regarding its application[259–261]. To ensure that the benefits of genomic nephrology are available to all patients with kidney disease, it is imperative that minority populations have equal access to participation in genetic research and to clinical genetic assessment. Ongoing efforts to identify and address existing barriers to participation, perform sequencing studies in diverse populations, and develop educational materials tailored to individuals of varied backgrounds will help to achieve these aims[262].

Resource-limited settings

In low-income and middle-income countries (LMICs), access to clinical screening and care, including genetic testing, can often be limited[263–265]. Thus, individuals with hereditary nephropathies are likely underdetected and cannot access appropriate care. Several strategies have been recommended to address these disparities[156,266]. Provision of logistical and technical support will help to build national registries, biobanks, and other infrastructure and to establish standards of care. Electronic modes of communication can enable international collaboration with global experts in rare nephropathies, helping local physicians to create and implement best practices for patients. Proposed approaches to implementing genetic testing in LMICs emphasize providing clinically useful and cost-effective services tailored to fit the needs of the given population. Strategies include targeted testing for founder variants in genes associated with medically actionable autosomal recessive nephropathies that have high prevalence in the region (for example, screening of the *MEFV* gene, associated with familial Mediterranean fever (OMIM 134610, 249100), in the southeast Mediterranean[267]) and focused NGS panels containing the genes that are most commonly mutated in the disorder (for example, a panel including *NPHS1, NPHS2*, and *WT1* for suspected hereditary early-onset nephrotic syndrome). Although WES or WGS are becoming the standard for work-up of undiagnosed disorders, the high cost and limited availability of these technologies are substantial barriers to their use in LMICs. Mendeliomes have been recommended as a means of providing broad assessment of the disease-associated genome at a feasible cost and have shown promising results as diagnostics in this context[268,269].

Organizations such as Human Heredity and Health in Africa (H3Africa) and the Mexico National Institute of Genomic Medicine (INMEGEN) have already begun to implement such strategies, which will help to make the benefits of genomic medicine available globally. The H3Africa Kidney Disease Research Network initiative centres upon a case–control study of 4,000 patients with CKD and 4,000 healthy controls across four sub-Saharan African nations[270]. The clinical diagnoses to be studied include SRNS, biopsy-proven glomerulopathy, CKD of unknown aetiology, and hereditary glomerulopathies. Patients will undergo comprehensive clinical work-up, including genetic testing, with long-term follow-up over a period of 5 years. Importantly, the H3Africa consortium is developing a new

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

genotyping array to ensure maximal coverage of the highly genetically diverse African genome[271]. In addition, the consortium aims to build the resources needed to support genomic nephrology in Africa through training physicians and researchers and establishing biorepositories and sequencing facilities. This initiative will provide critical data regarding the genetic architecture of kidney disease and help to build a strong foundation for genomic nephrology in the region, providing a model for subsequent global efforts.

Paediatric genetic testing

As early-onset CKD is enriched for genetic aetiologies, genetic testing has been advocated as a first-line diagnostic for paediatric nephropathy[4,156]. The discussion to date has overwhelmingly focused on the diagnostic value of genetic testing for this population; however, the ethical implications and psychosocial impact of genetic testing in minors must also be addressed. Important issues include the age at which consent for testing should be provided by the child rather than by the parents, how to balance the potential for early clinical intervention versus the right of the patient to an open future[272], how to explain the primary findings to the patient, and the potential impact of knowledge of a genetic condition on the psychoemotional development and health of the child.

With the advent of genome-wide testing, the question has also arisen of how secondary findings should be treated among paediatric patients. The majority of the genes designated by the ACMG for analysis of medically actionable secondary findings are associated with hereditary cancers and other adult-onset conditions. Thus, the value of returning such results to paediatric patients is debatable. Although this knowledge could resolve parental anxiety regarding risk status and inform family planning, it threatens the right of the patient to autonomy and confidentiality and could result in considerable psychological harm[273]. Moreover, no clear consensus guidelines currently exist regarding this topic. The American Academy of Pediatrics recommends deferring predictive testing for later-onset conditions until adulthood, whereas the ACMG advises that the decision be made on a per-family basis[274,275]. Matters become even more complex with adolescents, as they may want to decide independently of their parents or other family members and/or may not want to have their genetic findings shared with their families[276]. Longitudinal study of the medical and psychosocial impact of genetic testing on paediatric patients and their families will help to guide creation of best practice guidelines regarding these topics.

Legal protection

In 1997, the United Nations Educational, Scientific and Cultural Organization (UNESCO) Declaration on the Human Genome and Human Rights ruled that genetic information should not be used to infringe upon “human rights, fundamental freedoms, and human dignity”, establishing an international stance against `genetic discrimination` (GD). In Europe, the 1997 Convention on Human Rights and Biomedicine and the 2012 Charter of Fundamental Rights of the European Union protect individuals against GD; under the primacy of European law, these protections take precedence over any conflicting national legislation, and many European nations have also created their own anti-GD statutes[277,278]. Other nations, such as Australia, the US, and Canada, have also passed anti-GD legislation. By contrast, anti-GD protection remains scant in Latin America, Africa, and the Middle

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

East, with the exception of Mexico, Chile, Malawi, and Israel[278]. Anti-GD legislation is similarly sparse across Asia, despite the strong presence of genetic research and personalized medicine in many Asian nations; to date, only South Korea and Taiwan have created specific prohibitions[278,279].

Legal protection for individuals undergoing genetic testing has focused on regulating the use of genetic findings by insurers and employers, reflecting concerns that these parties will use genetic information to deny individuals employment and/or associated insurance benefits[277,280]. However, the degree of legal protection varies substantially between nations. The 2016 Council of Europe recommendation requires insurers to justify use of all "health-related personal data" and prohibits insurers from requiring individuals to undergo genetic testing for insurance purposes[281]. Similarly, in Israel, the Genetic Information Law of 2000 bars use of genetic information for employment and insurance purposes[282]. Other countries take a looser stance; in the UK, for instance, insurers may use genetic test results if approved by the government[283], and in Canada, insurers have pledged to not "use genetic test results for life insurance coverage of $250,000 or less" (REF. 284).

In the USA, the lack of a national health-care system has magnified concerns, as individuals usually obtain employment-based insurance. In an effort to protect individuals against GD, in 2008, the US government enacted the Genetic Information Nondiscrimination Act (GINA), which forbids employers and health insurers to request genetic information from individuals and/or discriminate against them on the basis of any available genetic information. These protections do not, however, extend to other types of insurance, including life and disability coverage, and have been threatened by subsequent legislative initiatives. For example, under the 2017 H.R.1313 bill, employers would be able to request that their employees undergo genetic testing and share their results as part of a workplace wellness programme. Employees who refuse could face increased yearly insurance premiums, a substantial financial penalty that some argue would effectively force individuals into participating, undermining their autonomy and privacy. Conversely, limited legal protection can also discourage individuals from choosing to participate in genomic research for fear that the data gathered would have to be shared and could be used to discriminate against them. Such fears could cause people to forgo potentially medically valuable tests and obstruct the clinical research needed to better understand and treat a variety of health conditions[285].

Conclusions

Genomic medicine aims to use genetic information about patients to inform their clinical care. CMA and NGS have revolutionized nephrology research, illuminating the molecular pathogenesis of a variety of genetic kidney diseases, and have great potential clinical utility across a wide range of indications. The remaining questions are how to fill in the substantial gaps in knowledge and how to translate what is currently known into personalized care. Strategies that may help to accomplish these aims include multicentre sequencing studies in large, diverse all-cause CKD cohorts; the establishment of expert working groups to create disease-specific standards for required pretest phenotypic information, genes assessed and variant interpretation; utilization of genetic stratification to better power clinical trials; and

Author Manuscript

Author Manuscript

Author Manuscript

Author Manuscript

the inclusion of geneticists and genetic counsellors in multidisciplinary care teams (TABLE 4).

While pursuing these efforts, it is imperative that we remain mindful of the limitations of our knowledge. Genetic testing does not give absolute answers, but rather provides a probabilistic biomarker, the meaning of which must be interpreted in the overall genomic and clinical context[286]. In many cases, the ‘one gene, one disease’ model does not apply owing to the presence of genetic and environmental modifiers. Thus, physicians and geneticists must incorporate diagnostic sequence interpretation with traditional tools such as clinical history and renal biopsy as well as with other sources of omic data, all of which can provide crucial insight into the genetic findings. Through considering each individual comprehensively in his or her own unique clinical context, genomic nephrology can deliver truly personalized care for patients with kidney disease.

Glossary

Heritability

The proportion of interindividual variation in a given trait that is due to genetic factors.

Chromosomal microarray (CMA)

A technique to detect copy number variants by hybridizing a patient’s DNA to probes corresponding to various regions of the genome; the hybridization pattern for a given probe reflects the number of copies that the patient has of that genomic region.

Next-generation sequencing (NGS)

Simultaneous sequencing of multiple DNA segments; also known as massively parallel sequencing.

Genome

The entirety of an individual’s DNA. The genome is divided into smaller protein-coding segments called genes.

Genetic testing

The assessment of DNA sequence variation. Genetic testing can be performed at the level of a single variant, a gene, multiple genes, or the entire genome.

Genomic medicine

An emerging branch of medicine that uses information about an individual’s genome to inform their clinical care, including diagnosis, prognosis, and treatment.

Genetic diagnosis

The hereditary aetiology of a patient’s presentation, as identified by genetic testing.

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

Single-nucleotide variants (SNVs)

Changes of single bases (nucleotides) in a DNA sequence. SNVs can lead to an altered amino acid sequence in the encoded protein (nonsynonymous variants) or leave the sequence unchanged (synonymous variants).

Insertions or deletions

The gain or loss of bases in a DNA sequence, resulting in an altered amino acid sequence in the encoded protein.

Structural variants

Large (≥1 kb) DNA variants that include balanced (for example, inversions or reciprocal translocations) and imbalanced alterations (for example, copy number variants).

Sanger sequencing

A DNA sequencing method that uses labelled chain-terminating dideoxynucleotides to identify the nucleotides in the DNA strand being sequenced. This method generates a sequence chromatogram that can be analysed to detect genetic variants.

Targeted next-generation sequencing panels

Next-generation-sequencing-based analysis of a set of genes commonly associated with the patient’s clinically suspected phenotype.

Whole-exome sequencing (WES)

Next-generation-sequencing-based analysis of the exome — the protein-coding regions of the genome that contain the majority of known causal variants for Mendelian disorders.

Whole-genome sequencing (WGS)

Next-generation-sequencing-based analysis of the whole genome, including protein-coding and non-coding regions.

Karyotyping

A technique used to detect large genomic imbalances through visual inspection of stained chromosomes using a microscope at high magnification (× 1,000).

Copy number variants (CNVs)

Structural variants that results in gain or loss of DNA at the relevant locus.

Array comparative genomic hybridization

A type of chromosomal microarray in which patient and control DNA are labelled with different coloured fluorescent dyes and cohybridized to a single DNA probe in order to directly compare copy number at that genomic region.

Single-nucleotide polymorphism arrays

A type of chromosomal microarray in which a patient’s DNA is hybridized to DNA probes corresponding to single-nucleotide polymorphisms and the hybridization pattern is compared with previously analysed controls. This type of chromosomal microarray can detect a patient’s genotype in addition to copy number at a given genomic region.

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

Balanced chromosomal rearrangements

Chromosomal rearrangements that do not cause a net loss or gain of genetic material.

Sequencing coverage and depth

In this Review, sequencing coverage denotes the percentage of bases in the DNA region targeted by sequencing that is sequenced a given number of times. Sequencing depth refers to the average number of times that a given nucleotide is read in a set of DNA sequence reads. Higher coverage and depth means that more of the targeted genomic region has been sampled a greater number of times, increasing the accuracy of the resulting data.

Secondary findings

Genetic findings that are not related to the primary indication for testing; also called incidental findings.

Multiplex ligation-dependent probe amplification

A technique in which patient DNA is hybridized to two oligonucleotide probes, corresponding to the 5′ and 3′ ends of the DNA, which are then ligated and PCR-amplified using a fluorescently labelled primer. The resulting PCR products are size-separated using capillary electrophoresis, and the fluorescent signal intensity is compared between the probe and the patient’s DNA to determine copy number at that region. In addition to identifying copy number variants, this technique can detect mosaicism for a copy number variant and DNA methylation status.

Variants of uncertain significance (VUSs)

Genetic variants that have an unclear association with a given disorder owing to insufficient or conflicting evidence.

Phenotypic expansions

Phenotypic expansions occur when mutations in a gene that is classically associated with one phenotype are demonstrated to cause another clinically distinct phenotype.

Allele

Within each chromosome, the DNA sequence at a given region can vary; these variants are alleles.

Missense variant

Single-nucleotide variant that leads to the replacement of the amino acid normally encoded with another amino acid.

Haploinsufficiency

The state that arises when one copy of a gene is deleted or otherwise inactivated and the single remaining copy is insufficient to produce the amount of gene product needed to maintain normal function, leading to an abnormal (disease) phenotype.

Loss-of-function variation

DNA sequence alteration that leads to a protein with severely reduced or no function. Genetic variants that result in a prematurely truncated protein, such as nonsense variants, generally cause loss of function; however, missense variants can also have this effect.

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

Nonsense variant

Single-nucleotide variant that leads to the replacement of the amino acid normally encoded with a stop codon, leading to a prematurely truncated protein.

Variant phasing

Determining whether two variants in an individual's genome are both on the same copy of the gene (in cis) or on different copies of the genes (in trans) by use of parental testing. If two variants in a gene associated with a recessive disorder are in *trans*, they are more likely to be causal for the disorder, as they will impact both copies of the gene.

Allele frequency

The incidence of an allele in a population. Allele frequency is calculated by dividing the number of times that the allele is found by the total number of chromosomes. The allele frequency can be used to assess the rarity of a certain allele to help ascertain its pathogenicity during clinical sequence interpretation.

Penetrance

The proportion of individuals with a certain genetic variant who display the phenotype that is associated with this variant.

Genetic discrimination (GD)

Differential treatment of individuals on the basis of their genetic information.

Nephrol. 2017. http://dx.doi.org/10.1681/ASN.2016101108 This article shows that paediatric patients with CKD owing to genomic disorders have poorer neurocognitive function than those without independent of the severity of renal dysfunction. These results suggest that for some patients, neurocognitive impairment and nephropathy have a common genetic basis, informing clinical expectations and management.

152. Vivante A, et al. Exome sequencing discerns syndromes in patients from consanguineous families with congenital anomalies of the kidneys and urinary tract. J. Am. Soc. Nephrol. 2017; 28:69–75. This article describes the successful use of WES to achieve a molecular diagnosis in genetically unresolved cases of CAKUT. Notably, 44% of diagnosed patients had mutations in genes not classically associated with CAKUT, highlighting the utility of genome-wide testing to pinpoint a specific — and often unexpected — disease aetiology among patients with nonspecific phenotypes. Key points

- Inherited aetiologies are responsible for ~10% of adult end-stage renal disease and >70% of paediatric hephropathy; sequencing studies of large cohorts will shed further light on genetic contributions across different forms of kidney disease
- In addition to ending the ‘diagnostic odyssey’, a genetic diagnosis can provide a deeper understanding of disease pathogenesis, inform prognosis, and guide clinical management
- Genetic testing is currently recommended for patients with early-onset nephropathy and/or other clinical features consistent with an inherited form of disease as well as for evaluation of living kidney donors
- Development of disease-specific guidelines and use of population genetic data will help to facilitate accurate clinical sequence interpretation; nevertheless, patient-level assessment results in the continued need for expert judgement
- The broadening clinical use of genetic testing in nephrology has raised questions regarding the return of results, physician education, testing across different patient subpopulations and many other practical and ethical issues
- Interdisciplinary research and dialogue will help to address unresolved challenges and inform the creation of best practice guidelines for genomic medicine in nephrology

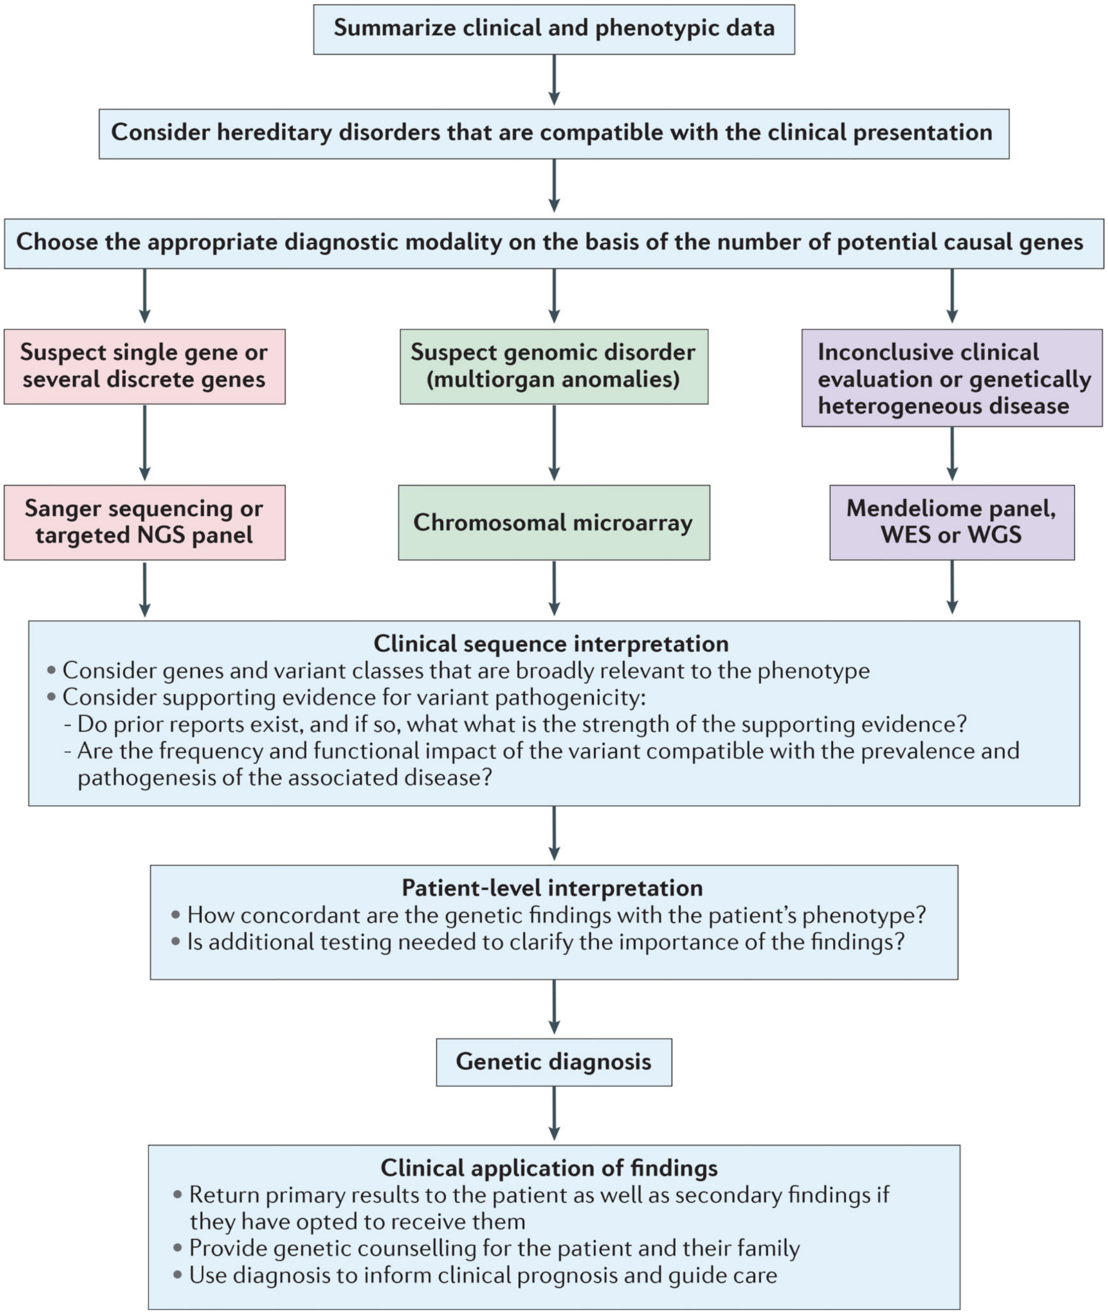
Genetic testing for *APOL1* risk alleles

A rapidly developing area in nephrology is the issue of genetic testing for *APOL1* risk alleles: two common coding variants that strongly influence the risk of multiple forms of nephropathy among individuals of sub-Saharan African descent. *APOL1*-mediated disease has been reported to follow a recessive model, with individuals with these two risk variants displaying a 7 to 10-fold higher risk of hypertension-associated end-stage renal disease (ESRD) and a 10 to 17-fold higher risk of focal segmental glomerulosclerosis (FSGS)-associated ESRD than those with one or no risk variants[251,287]. Subsequently, the *APOL1* risk genotypes have also been associated with increased risk of other forms of kidney disease, progression to ESRD, and allograft failure[250,252]. They might also impact risk of cardiovascular disease, although the precise nature of this association remains to be determined as both positive and protective effects have been reported[288].

Importantly, penetrance is variable; although the *APOL1* risk genotypes confer substantially higher odds of nephropathy than nonrisk genotypes, only a minority of individuals with *APOL1* risk genotypes develop kidney disease[289]. This finding suggests that *APOL1*-mediated kidney disease follows a two-hit model, whereby a secondary factor is required in addition to the risk genotype for disease development[250,252]. Such secondary factors might include environmental or genetic modifiers, including risk variants at other loci[290], and immunological triggers, such HIV infection[291,292]. Given the complexity of *APOL1*-mediated kidney disease, the clinical utility of the risk genotypes remains unclear.

The 2017 Kidney Disease: Improving Global Outcomes (KDIGO) guidelines recommend *APOL1* testing for candidate kidney donors but acknowledge that the evidence base is moderate, as insufficient evidence exists regarding the impact of donation on lifetime risk of nephropathy[160]. Additional investigation, including of the long-term outcomes of individuals with *APOL1* risk genotypes, allograft survival from donors with the *APOL1* risk genotypes, and the pathobiology underlying *APOL1*-mediated disease, will help guide how to best utilize *APOL1* risk variant status in nephrology[293].

Author Manuscript Author Manuscript Author Manuscript Author Manuscript



Summarize clinical and phenotypic data
Consider hereditary disorders that are compatible with the clinical presentation
Choose the appropriate diagnostic modality on the basis of the number of potential causal genes
Suspect single gene or several discrete genes
Suspect genomic disorder (multiorgan anomalies)
Inconclusive clinical evaluation or genetically heterogeneous disease
Sanger sequencing or targeted NGS panel
Chromosomal microarray
Mendeliome panel, WES or WGS
Clinical sequence interpretation
• Consider genes and variant classes that are broadly relevant to the phenotype
• Consider supporting evidence for variant pathogenicity:
- Do prior reports exist, and if so, what what is the strength of the supporting evidence?
- Are the frequency and functional impact of the variant compatible with the prevalence and pathogenesis of the associated disease?
Patient-level interpretation
• How concordant are the genetic findings with the patient's phenotype?
• Is additional testing needed to clarify the importance of the findings?
Genetic diagnosis
Clinical application of findings
• Return primary results to the patient as well as secondary findings if they have opted to receive them
• Provide genetic counselling for the patient and their family
• Use diagnosis to inform clinical prognosis and guide care

Figure 1. The genomic nephrology workflow: genetic diagnosis and clinical application

The first step in obtaining a genetic diagnosis for a patient with kidney disease is to characterize their disease phenotype by summarizing their clinical history and other relevant data (for example, findings from biochemical, imaging, and histopathological studies). This phenotype is then used to guide the choice of genetic testing modality. Among patients with genetically heterogeneous disease aetiologies, clinically ambiguous phenotypes, or null results obtained using targeted forms of genetic testing such as Sanger sequencing or targeted next-generation sequencing (NGS) panels, increasingly broad sequencing approaches can be applied, including Mendeliome panels, which can detect variants in all

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

known disease-causing genes; whole-exome sequencing (WES), which can detect variants in all coding regions; and whole-genome sequencing (WGS), which can detect variants in all coding and non-coding regions. Clinical sequence interpretation should be performed according to consensus guidelines[66,67,182]. This process involves identifying genes that are relevant to the phenotype of the patient, prioritizing variants on the basis of prior reports in disease cases as well as compatibility with the prevalence and genetic pathogenesis of the associated disease, and assessing the concordance between the genetic findings and the clinical phenotype. If deemed diagnostic, these primary findings, together with secondary findings if the patient has opted to receive them, can be returned and used to inform prognosis and guide personalized care, including targeted work-up and surveillance, choice of therapy, referral for clinical trials and family counselling.

Table 1

Major genetic testing modalities: indications and limitations

Modality	Scope	Indications for use	Examples	Advantages	Disadvantages
Sanger sequencing	Detection of SNVs and small indels (<10 bp) within a DNA segment of <1 kb	• Confirmation of NGS findings • Regions refractory to NGS, such as GC-rich, highly repetitive segments • Patients whose phenotype is indicative of a disorder caused by mutations in one specific gene	• Confirm frameshift *COL4A3* variant detected by NGS • Diagnostic testing for Fabry disease • Detect *CTNS* mutation (nephropathic cystinosis) in a patient with corneal cystine crystals and Fanconi syndrome	• High analytical accuracy • Easier and faster sequence interpretation compared with multigene testing enables faster turnaround time • No risk of secondary findings	• Resolution <1 kb; cannot detect larger structural variants • Increasingly time- and cost-inefficient with increasing gene length and/or number of genes tested
Chromosomal microarray	Genome-wide detection of CNVs ≥200–400 kb	Patients with phenotypes commonly resulting from genomic imbalances, such as multiple congenital anomalies	• Detect whole-gene deletion of *HNF1B* in a patient with renal hypodysplasia and autism • Detect 22q11.2 deletion (DiGeorge syndrome) in a patient with renal agenesis and neonatal hypocalcaemia	• Higher resolution enables detection of CNVs missed by karyotyping • Genome-wide CNV detection increases diagnostic sensitivity	• Cannot detect SNVs, indels, and small CNVs • Limited ability to detect balanced chromosomal rearrangements, low-grade somatic mosaicism, and CNVs in certain regions (such as pseudogenes and repetitive elements)
Targeted NGS panels	Detection of SNVs and small indels (<1 kb) within genes of interest for the clinically suspected phenotype	• Patients with phenotypes that are fairly specific for a particular disorder • Disorders with low genetic and/or phenotypic heterogeneity	• Testing *AGXT*, *HOGA1*, and *GRHPR* for primary hyperoxaluria in a patient with childhood-onset calcium oxalate urolithiasis • Testing for *COL4A3*, *COL4A4*, and *COL4A5* mutations in a patient with suspected Alport syndrome	• Can be optimized to ensure sufficient coverage of variants in targeted regions • Interrogation of genes that are related to the clinical indication facilitates interpretation and minimizes risk of secondary findings	• Testing a limited number of genes decreases diagnostic sensitivity, especially for genetically and/or phenotypically heterogeneous disorders • Challenges of panel design (gene selection and need for frequent updates) • Minimal capacity for sequence reanalysis
Whole-exome sequencing	Detection of SNVs and small indels (<1 kb)	• Patients with highly genetically heterogeneous or	• NPHP-RC[122,123] • Diagnosis of congenital chloride	• Unbiased approach increases diagnostic sensitivity	• Lower analytical sensitivity and specificity than whole-genome sequencing

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

Modality	Scope	Indications for use	Examples	Advantages	Disadvantages
	within coding regions of the genome	nonspecific phenotypes • CKD of unknown aetiology • Patients left undiagnosed by targeted NGS panels	diarrhoea in an unresolved case of presumed Bartter syndrome[148] • Diagnosis of *LMX1B* glomerulopathy in familial ESRD of unknown origin[165]	• Interrogation of the coding regions that are enriched for known disease-causing mutations is a cost-effective approach to genome-wide testing • Genome-wide scope enables sequence reanalysis and discovery of novel genes	owing to limited coverage of certain regions and inability to accurately call certain types of variants (such as indels) • Approach can lead to multiple candidate variants, increasing time required for interpretation and need for follow-up testing • Burden of secondary findings in genes unrelated to the primary indication for testing
Whole-genome sequencing	Detection of SNVs and small indels (<1 kb) within coding and non-coding regions of the genome	• Patients with highly genetically heterogeneous phenotypes • Patients with nonspecific phenotypes • CKD of unknown aetiology • Patients left undiagnosed by all other genetic testing modalities	• Detection of causal intronic variants, for example, in a genetically unresolved case of Gitelman syndrome[106] • Genetic diagnosis of ADPKD (owing to high sequence homology of *PKD1*)[110] • Detection of causal balanced translocations for congenital anomalies[294,295]	Superior diagnostic and analytical sensitivity to whole-exome sequencing owing to its ability to assess SNVs, indels, and CNVs in coding and non-coding regions and more complete per-base coverage	• Difficulty of interpreting non-coding variants • Large amount of data generated results in substantial time and monetary costs, hindering return of results • Burden of secondary findings in genes unrelated to the primary indication for testing • Burden of long-term sequence data storage

ADPKD, autosomal dominant polycystic kidney disease; ADTKD-*MUC1*, autosomal dominant tubulointerstitial kidney disease due to mutations in *MUC1*; *AGXT,* alanine-glyoxylate aminotransferase; CKD, chronic kidney disease; CNV, copy number variant; COL4A, collagen type IV α-chain; *CTNS*, cytinosin, lysosomal cystine transporter; ESRD, end-stage renal disease; GC, guanine-cytosine; *GRHPR*, glyoxylate and hydroxypyruvate reductase; *HOGA1*, 4-hydroxy-2-oxoglutarate aldolase 1; *HNF1B*, HNF1 homeobox B; *LMX1B*, LIM homeobox transcription factor 1β; *MUC1*, mucin 1, cell surface associated; NGS, next-generation sequencing; NPHP-RC, nephronophthisis-related ciliopathy; *PKD1*, polycystin 1, transient receptor potential channel interacting; SNVs, single-nucleotide variants.

Table 2

Examples of the clinical utility of genetic diagnoses in nephrology

Indication	**Genetic finding**	**Genetic diagnosis**	**Clinical impact**	**Refs**
Steroid-resistant nephrotic syndrome	Homozygous Fin-major mutation in *NPHS1*	Nephrotic syndrome type 1 (OMIM 256300)	Increased risk of post-transplant disease recurrence	296,297
	COQ2 mutation	CoQ_{10} deficiency 1 (OMIM 607426)	CoQ_{10} supplementation can attenuate proteinuria and extrarenal complications such as encephalopathy	298,299
	COL4A3 or COL4A4 missense mutation	Alport syndrome (OMIM 104200; 203780) or TBMD (OMIM 141200)	• Distinguishes between autosomal (*COL4A3* or *COL4A4*) and X-linked (*COL4A5*) inheritance, informing family counselling • Missense mutations are associated with less severe disease and slower progression to ESRD than loss-of-function mutations • Avoid immunosuppression (a commonly used therapy for nephrotic syndrome)	79, 300–302
Cystic renal dysplasia	17q12 deletion	Renal cysts and diabetes syndrome (OMIM 137920)	Multisystem work-up for associated extrarenal complications, including testing for diabetes, exocrine pancreatic insufficiency, hepatic function, neurological anomalies, and/or neurocognitive impairment	133,134, 303
Nephrolithiasis	*APRT* mutation	APRT deficiency (OMIM 614723)	Xanthine dehydrogenase inhibition to prevent crystalline nephropathy and allograft loss	304,305
Episodic hypertension	*SDHD* mutation	Hereditary paraganglioma-pheochromocytoma syndrome (OMIM 168000)	• Imaging studies to screen for additional tumours • Catecholamine antagonists and/or surgical tumour resection • Knowledge of parent-of-origin effect due to maternal imprinting informs genetic counselling • Lower risk of malignancy than other genetic causes of familial paragangliomas-pheochromocytoma syndromes informs prognosis	306,307
Failure to thrive, hepatomegaly, and hyperuricemia	*G6PC* mutation	Glycogen storage disease Ia (OMIM 232200)	• Dietary therapy (frequent meals, nasogastric tube, and/or raw starch to prevent hypoglycaemia; oral bicarbonate and avoidance of fructose and glucose to prevent acidosis)	308,309

Indication	Genetic finding	Genetic diagnosis	Clinical impact	Refs
			- Surveillance for hepatic adenoma; liver transplant may be needed	

APRT, adenine phosphoribosyltransferase; *COL4A*, collagen type IV α-chain; CoQ$_{10}$, Coenzyme Q$_{10}$; *COQ2*, coenzyme Q2, polyprenyltransferase; ESRD, end-stage renal disease; G6PC, glucose-6-phosphatase catalytic subunit; *NPHS1*, nephrin; SDHD, succinate dehydrogenase complex subunit D; TBMD, thin basement membrane disease.

Resources for diagnostic sequence interpretation and clinical application

Resource	**Description**	**Website(s)**
Summarize patient data		
PhenoTips	• Web interface for clinicians to enter patient data and map symptoms to HPO terminology • Suggests candidate OMIM disorders and associated gene panels on the basis of phenotypic information	https://phenotips.org
Linking Open Data for Rare Diseases	• Web database that helps to code rare diseases by use of Orphanet, HPO, and OMIM data; provides information on epidemiology, inheritance, and characteristic features • Users can browse by disease name, medical specialty, signs or symptoms, and organ system(s) affected	https://bioportal.bioontology.org/projects/LORD
KCCG Patient Archive	• Web interface for clinicians to securely enter and store patients' clinical and genetic data and share these with other clinicians • Stores filtered summary results of genetic testing, facilitating writing of≈clinical genetic notes and return of results	http://www.patientarchive.org
Choose genes to analyse		
OMIM	• Database of >5,000 Mendelian disorders and >15,000 genes derived from curation of the primary literature • Provides an overview of each disorder and the associated genes and selected variants that have previously been reported	https://omim.org
Orphanet	• Database of rare diseases and associated genes, coded using HPO terminology • Diagnostic criteria are included for each disease to help users to gauge the relevance to a patient's phenotype	http://www.orpha.net
PanelApp	• Database of curated gene panels for particular indications, including a variety of renal disorders • Indicates the strength of association of each gene with the relevant phenotype; those with strong evidence are recommended for clinical testing panels	https://panelapp.extge.co.uk/crowdsourcing/PanelApp
ClinGen Gene-Disease Clinical Validity Classification Framework	Framework to assess the strength of association between a gene and a disease on the basis of evidence including the number of reported patients with variants in the gene and supporting experimental data	https://www.clinicalgenome.org/working-groups/gene-curation/projects-initiatives/clinical-validity-classifications
Prioritize variants		
ExAC and gnomAD	• ExAC is a database of WES data from 60,706 individuals; its successor, gnomAD, includes WES data from 123,136 individuals and WGS data from 15,496 individuals, encompassing seven major global populations • ExAC and gnomAD exclude related individuals and/or those with severe early-onset disorders but do include those sequenced as part of various adult-onset disease cohorts; individuals were not phenotyped in detail, so their disease status is unknown	• http://exac.broadinstitute.org • http://gnomad.broadinstitute.org
1000 Genomes	• Database of WGS data from 2,504 individuals from 26 different global populations; the data are of variable quality and include some related individuals • The participants are self-declared as healthy, but additional data regarding their health status was not collected	http://grch37.ensembl.org/index.html
Database of Genomic Variants	Database of >2.5 million structural variants detected in >22,300 healthy individuals; the relatedness status of participants is not mentioned	http://dgv.tcag.ca/dgv/app/home
ClinVar	• Open-access database of inherited and somatic genetic variants detected in individuals across a broad spectrum of disorders; contributors include diagnostic laboratories, other databases and research groups • Each variant is accompanied by assertions regarding its pathogenicity (or lack thereof) for the associated disease phenotype	https://www.ncbi.nlm.nih.gov/clinvar

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

Resource	Description	Website(s)
	- The number of stars accompanying an entry reflects the strength of supporting evidence for the classification, which varies considerably	
Human Gene Mutation Database	Database of disease-associated genetic variants, manually curated from review of the scientific literature; access to the most comprehensive version requires a paid subscription	https://www.qiagenbioinformatics.com/products/human-gene-mutation-database
Human Genome Variation Society	Repository for various disease and gene-specific databases, many of which are organized within the LOVD framework; individual databases vary in the amount and quality of information provided regarding the variants deposited	- http://www.hgvs.org/content/databases-tools - http://www.lovd.nl
Variant Effect Predictor	Software tool that predicts the impact of a genetic variant on the encoded protein and assesses its predicted pathogenicity by use of various *in silico* algorithms	http://www.ensembl.org/Tools/VEP
Uniprot	Protein database; users can query genes to see whether a variant is located in a conserved domain or has experimental data supporting an effect on protein function	http://www.uniprot.org
Patient-level interpretation

Abstract

Background: *Trypanosoma brucei gambiense* is the causative agent of chronic Human African Trypanosomiasis or sleeping sickness, a disease endemic across often poor and rural areas of Western and Central Africa. We have previously published the genome sequence of a *T. b. brucei* isolate, and have now employed a comparative genomics approach to understand the scale of genomic variation between *T. b. gambiense* and the reference genome. We sought to identify features that were uniquely associated with *T. b. gambiense* and its ability to infect humans.

Methods and Findings: An improved high-quality draft genome sequence for the group 1 *T. b. gambiense* DAL 972 isolate was produced using a whole-genome shotgun strategy. Comparison with *T. b. brucei* showed that sequence identity averages 99.2% in coding regions, and gene order is largely collinear. However, variation associated with segmental duplications and tandem gene arrays suggests some reduction of functional repertoire in *T. b. gambiense* DAL 972. A comparison of the variant surface glycoproteins (VSG) in *T. b. brucei* with all *T. b. gambiense* sequence reads showed that the essential structural repertoire of VSG domains is conserved across *T. brucei*.

Conclusions: This study provides the first estimate of intraspecific genomic variation within *T. brucei*, and so has important consequences for future population genomics studies. We have shown that the *T. b. gambiense* genome corresponds closely with the reference, which should therefore be an effective scaffold for any *T. brucei* genome sequence data. As *VSG* repertoire is also well conserved, it may be feasible to describe the total diversity of variant antigens. While we describe several as yet uncharacterized gene families with predicted cell surface roles that were expanded in number in *T. b. brucei*, no *T. b. gambiense*-specific gene was identified outside of the subtelomeres that could explain the ability to infect humans.

Introduction

Trypanosoma brucei subsp. *gambiense* is the causative agent of Human African Trypanosomiasis (HAT), or sleeping sickness, which is a vector-borne disease restricted to rural areas of sub-Saharan Africa. Trypanosomiasis in humans and livestock imposes substantial morbidity, representing a major impediment of agricultural production in the affected areas [1], and is fatal where untreated. The World Health Organization estimated in 1998 that up to 60 million people are at risk in approximately 250 distinct foci [2], although under-reporting has been estimated as high as 40% in some foci [3]. *T. b. gambiense* is the most clinically relevant sub-species, causing over 90% of all human disease. The gambiense disease is typically chronic, often lasting several years with few severe signs and symptoms until the late stage of nervous system involvement. *T. b. gambiense* is sensitive to treatment with pentamidine (early stage) and eflornithine (late stage), drugs which are frequently ineffective against *T. b. rhodesiense* [4], although the underlying biochemical reasons for these differences are unknown. Combination therapies against the late stage disease have performed encouragingly [5] but few drugs are available. Furthermore, unpleasant and in some cases severe side effects often result in poor patient compliance. Hence, new molecular targets are required to supply current drug discovery programmes [6].

T. brucei is subdivided into three subspecies based on infectivity to humans, pathogenicity and geographical distribution. *T. b. gambiense* and *T. b. rhodesiense* are human pathogens, causing Human African Trypanosomiasis (HAT) in West/Central and East Africa respectively. *T. b. brucei* cannot by definition infect

Author Summary

Sleeping sickness, or Human African Trypanosomiasis, is a disease affecting the health and productivity of poor people in many rural areas of sub-Saharan Africa. The disease is caused by a single-celled flagellate, *Trypanosoma brucei*, which evades the immune system by periodically switching the proteins on its surface. We have produced a genome sequence for *T. brucei gambiense*, which is the particular subspecies causing most disease in humans. We compared this with an existing reference genome for a non-human infecting strain (*T. b. brucei* 927) to identify genes in *T. b. gambiense* that might explain its ability to infect humans and to assess how well the reference performs as a universal plan for all *T. brucei*. The genome sequences differ only due to rare insertions and duplications and homologous genes are over 95% identical on average. The archive of surface antigens that enable the parasite to switch its protein coat is remarkably consistent, even though it evolves very quickly. We identified genes with predicted cell surface functions that are only present in *T. b. brucei* and have evolved rapidly in recent time. These genes might help to explain variation in disease pathology between different *T. brucei* strains in different hosts.

humans and is found in a wide range of wild and domestic mammals. The human pathogens have also been found in various animal species and HAT caused by *T. b. rhodesiense* in East Africa is recognized as a zoonosis. *T. b. gambiense* comprises two groups; a genetically homogeneous group to which the majority of isolates belong (group 1), and a second represented by a handful of isolates from West Africa (group 2). Group 1 *T. b. gambiense* strains have the smallest genomes in the *T. brucei* species complex, having 71–82% of the highest DNA content measured for *T. b. brucei* [7–8]. Pulse-field gel analysis of *T. b. gambiense* chromosomes shows that few if any mini-chromosomes are present compared to the estimated 100 in *T. b. brucei* and *T. b. rhodesiense*, and the mini-chromosomes are also of a smaller size–average 25 kb in *T. b. gambiense* compared to 100 kb in *T. b. brucei* and *T. b. rhodesiense* [8–9].

Perhaps as a consequence of this reduced genome, *T. b. gambiense* also has a restricted repertoire of *Variant Surface Glycoprotein (VSG)* genes [8,10–12]. At any time, bloodstream form trypanosomes possess a surface glycoprotein coat formed through the expression of a single gene from a large archive of *VSGs* [13]. This coat obfuscates the host immune system by shielding the invariant surface epitopes from view and, when an immune response is inevitably raised against the VSG monolayer and the active *VSG* is replaced by another, it allows parasites expressing the novel variant to escape the immune response [13]. This periodic VSG 'switching', or *in situ* activation, is facilitated by transposition of inactive *VSG* into a dedicated expression site at the telomeres by gene conversion [13–15]. Although *VSG* repertoire is clearly very large [16–17], it is not known how *VSG* diversity accumulates over time and between strains. The *SRA* gene encodes a truncated VSG-like protein [18]; it is located within one specific *VSG* expression site and is expressed in Human serum-resistance clones of *T. b. rhodesiense* only [19]. Innate immunity to trypanosomes in Humans is conferred by a trypanolytic factor, apoL1 [20] and *SRA* has acquired a role in neutralizing the toxic effects of this protein [21]. Hence, when transcriptionally activated, *SRA* enables particular *T. b. rhodesiense* clones to infect Humans [22]. *SRA* is absent in *T. b. gambiense* [23] and the underlying basis for the trait of human infectivity here is as yet unknown. In *T. b. gambiense*, as yet the only example of a subspecies-specific gene is *TgsGP*, which encodes a 47 kDa VSG-like receptor protein, and is expressed in the flagellar pocket of bloodstream stage cells [24]. However, *TgsGP* is not associated with human infectivity in *T. b. gambiense* [25].

We produced an improved, high-quality draft genome sequence for *T. b. gambiense* DAL927 with the twin aims of identifying subspecies-specific genomic features that might contribute to our understanding of phenotypic variation and assessing the scale of genomic variation across *T. brucei*. This was achieved through comparison with the *T. b. brucei* 927 reference genome and we sought to evaluate the proficiency of this reference, ahead of the next generation of genome sequencing projects that will compare multiple isolates to scrutinize genetic divergence and genomic rearrangements in relation to disease. Our analyses show that the genome sequence of *T. b. gambiense* corresponds closely in gene order and content to the *T. b. brucei* 927 genome. Intraspecific genomic variation is largely associated with tandem or segmental duplications, among which we identify several subspecies-specific isoforms. Our final objective was to compare the *VSG* repertoires of *T. b. brucei* and *T. b. gambiense*, and so provide the first global perspective of how *VSG* diversity evolves on a genome scale. Details of the genome project describing the 'Minimum Information for Genome Sequences' are available online (http://genomesonline.org/GOLD_CARDS/Gi00917.html).

Methods

Accession numbers

The sequence of the *Trypanosoma brucei gambiense* genome has been submitted to the EMBL database under accession numbers FN554964- FN554974 inclusive.

Trypanosome stocks

The *T. b. gambiense* strain MHOM/CI/86/DAL972 was isolated from a patient in Côte d'Ivoire in 1986 and has been used routinely in laboratory studies since this time [26]. Bloodstream form trypanosomes were fed to tsetse *in vitro* and procyclics from infected midguts were established in culture and subsequently optically cloned. Procyclic form trypanosomes were grown in Cunningham's medium supplemented with 10% v/v heat-inactivated foetal calf serum, 5 µg/ml hemin and 10 µg/ml gentamycin at 27°C. High molecular weight DNA was purified by standard methods of phenol-chloroform extraction and alcohol precipitation.

T. b. gambiense genome sequencing and assembly

T. b. gambiense DNA was randomly sheared, size-selected DNA purified and subcloned into pUC19 plasmids (1.4 kb–4 kb inserts), as well as BAC vectors as previously described [27]. Inserts were sequenced by random sequencing using dye-terminator chemistry on ABI 3730 sequencing machines from both ends to generate paired end reads. There were 369,043 passed paired-end reads, producing roughly eight-fold coverage of the whole genome. Sequence reads were assembled using Phrap (www.phrap.org; P. Green, unpublished). Automated in-house software (Auto-Prefinish) was used to identify primers and clones for additional sequencing to close physical and sequence gaps by oligo-walking. Manual base checking and finishing was carried out using Gap4 (http://www.mrc-lmb.cam.ac.uk/pubseq/manual/gap4_unix_1.html). Regions containing repeat sequences or with an unexpected read depth were manually inspected. The assembled contigs were iteratively ordered and orientated against the *T. brucei* 927 genome sequence, with manual checking. Aided by information from orientated read-pairs, together with additional sequencing from selected large insert clones, we re-examined regions with apparent breaks in chromosomal colinearity for potential assembly errors.

Genome annotation

The human-curated annotation of the *T. b. brucei* 927 reference genome was transferred to the assembled *T. b. gambiense* genome on the basis of BLASTp matches and positional information using custom perl scripts. Subsequently, gene structure and functional annotation were manually inspected and further edited, where appropriate, using the Artemis software [28], as previously detailed [27]. The annotation of the *T. b. gambiense* genome can be viewed and searched via GeneDB (http://www.genedb.org/) and comparative chromosome maps for *T. b. brucei* and *T. b. gambiense* are available at TritrypDB (http://tritrypdb.org; [29]). Chromosomal sequences have been submitted to EMBL with the following accession numbers: FN554964-FN554974 inclusive.

Variation detection from sequence data

The *T. b. gambiense* capillary shotgun reads were aligned against the *T. b. brucei* 927 reference genome using SSAHA2 (http://www.sanger.ac.uk/Software/analysis/SSAHA2/). We discarded reads that mapped to more than one location on the reference genome, as well as pairs of reads that did not map in the correct orientation or to within 20% of the expected insert size of the library. In-house perl scripts were used to identify single nucleotide polymorphisms (SNPs) from the SSAHA alignments that adhered to a modified version of the Neighbourhood Quality Standard (NQS, [30]); we term this AltNQS. According to NQS, an acceptable SNP (or fixed difference) has a phred quality score of ≥23 and the 5 bases on either side of the SNP position have a quality score of ≥15. However, these strict criteria do not allow for multiple mismatches within the 11 bp window. To accommodate the higher levels of polymorphism, our AltNQS adheres to the same rules as NQS but allows for multiple SNPs within the 11 bp alignment window as long as the base quality of each SNP has a phred score of at least 23. To identify regions with significantly high SNP density on each chromosome, non-overlapping windows of 10 kb with at least 50% of read coverage were selected for analysis. For these windows, SNP density was calculated as the number of SNPs divided by the number bases covered in that 10 kb window. Using random sampling we estimated the mean and 97.5% confidence limit of mean SNP density. Regions with a value above the 97.5% quantile were identified as having significantly high SNP density values.

Tandem repeat recombination analysis

Tandem gene arrays in the *T. b. brucei* 927 genome with >3 gene copies have previously been defined, and are known to contain polymorphism that is affected by recombination [31]. We assessed the variation among tandem gene duplicates to identify subspecies-specific genes. For each of these arrays, the coding and 3′ UTR sequences were gathered from the corresponding regions of the *T. b. gambiense* genome sequence. The downstream limit of the 3′ UTR was defined by the polypyrimidine termination motif [32]. All *T. b. brucei* and *T. b. gambiense* sequences were aligned in ClustalX [33] and manually adjusted. Those arrays showing no variation or only corresponding isoforms in both subspecies (i.e., simple orthology) were discarded, leaving just those cases where a disparity in sequence diversity was apparent. To detect any ambiguity in phylogenetic relationships among sequences, each of these alignments was analyzed using SplitsTree v4.3 [34], which applies a Neighbour-Net method [35]) to estimate a phylogenetic network. Genetic distances were corrected for variation in base composition after excluding phylogenetically-uninformative characters. Each alignment was also analyzed using the pair-wise homoplasy index (PHI) test [36] that can detect multiple phylogenetic signals within an alignment and is robust in the presence of rate heterogeneity. A third method, the genetic algorithm for recombination detection (GARD, [37]) was applied to estimate the number and placement of recombination breakpoints along each alignment.

Comparison of the variant surface glycoprotein (VSG) repertoire

1258 predicted VSG protein sequences encoded in the *T. b. brucei* genome were compared with the *T. b. gambiense* 972 read library using pair-wise BLASTp searches. These included 36 *VSG*-related (*VR*) sequences that are structurally distinct from the bulk of canonical *VSG* [17]. Initially, all *VSG*-like sequences were extracted from the *T. b. gambiense* read library using BLASTx against whole VSG protein sequences. Each *T. b. brucei* VSG protein sequence was then individually BLAST-searched against this subset of *VSG*-like reads to determine its closest match in *T. b. gambiense*. A reciprocal comparison was carried out to confirm the relationship. To determine if a given gene was most closely related to a paralog in *T. b. brucei* or to an ortholog in *T. b. gambiense*, each *T. b. brucei* VSG protein sequence was also compared a combined database of *VSG* gene models and *VSG*-like reads using BLASTp. BioLayout Express 3D [38] was used to visualize the relative genetic distances between the 1258 *T. b. brucei* VSG sequences, using the BLAST scores derived from comparisons of each gene with all others, and a 70% cutoff to simplify the resulting network graph. To determine if *VSG* diversity is sub-structured according to life stage, nine VSG sequences known to be associated with metacyclic expression sites were BLAST-searched against all other (bloodstream-expressed) VSG and added to the network.

Results/Discussion

The *T. b. gambiense* genome was whole-genome shotgun sequenced to eight-fold coverage by paired-end capillary sequencing of plasmid and bacterial artificial chromosome (BAC) clones, resulting in an improved high-quality draft sequence. In comparison with the *T. b. brucei* 927 reference sequence, the two genomes are very similar in composition and structure, such that no protein coding sequence unique to *T. b. gambiense* could be found. However, coding sequences unique to *T. b. brucei* were found and the two genomes displayed other subtle differences in the diversity of repetitive regions such as segmental duplications, tandem gene arrays and strand switch regions, which document the scale of genomic variation across *T. brucei* subspecies.

The *T. b. brucei* reference is an effective template for the *T. b. gambiense* genome sequence

The draft genome assembly consists of 1768 contigs larger than 2 kb, amounting to 32.6 Mb of data. Of these, 281 contigs, totaling 22.1 Mb, were ordered and orientated against the *T. b. brucei* 927 reference genome. The remaining contigs encode additional copies of tandemly arrayed gene families as well as genes typically associated with subtelomeres such as expression site associated genes (*ESAGs*), variant surface glycoprotein (*VSG*) genes and the *ingi* transposable element. The gene models and annotation of an initial set of 9898 coding sequences located on core chromosomes (i.e., not in subtelomeres) were transferred to the *T. b. gambiense* genome on the basis of BLASTp matches and positional information using custom perl scripts.

When compared, the *T. b. brucei* and *T. b. gambiense* genome sequences are very similar in terms of content, gene order and sequence identity. The absence of potentially *gambiense*-specific sequences was confirmed by examining a Phrap assembly of those capillary reads that did not map against the *T. brucei* 927 reference genome. Analysis of $\sim$40,000 unmapped sequence reads using BLASTx showed that among them were features homologous to *VSG*, *ESAG* and *RHS* genes, as well as *ingi* retrotransposons, but no additional coding sequences that were missing from *T. b. brucei*. We examined the divergence of coding sequences and a frequency histogram of percentage nucleotide identity (Fig. 1) shows that 86.4% of genes vary by less than 1% from their *T. b. brucei* ortholog (mean average nucleotide identity $= 99.2\%$). Non-coding regions were more divergent, which is unsurprising given that they are probably under weaker purifying selection, but still remained 95.4% identical on average. However, against this general background of correspondence there are 69 pairs of orthologs that display significantly greater evolutionary change, (i.e., they are among the 5% most divergent orthologs with a nucleotide identity $<95.2\%$). 35 of these gene pairs are *VSG* sequences; these surface glycoproteins are exposed to frequent gene conversion and evolve rapidly [16–17], so naturally, they display lower sequence identities of $\sim$60–85%. However, they still display reciprocal top BLAST hits with *T. b. brucei* sequences. Also among these divergent gene pairs are 17 uncharacterized genes, 10 of which are predicted to encode cell-surface targeted proteins. For example, Tb927.5.4010/Tbg972.5.4300 (92.7% identical) and Tb10.70.1280/Tbg972.10.6310 (93.7% identical) are both located at strand-switch regions and encode hypothetical proteins with predicted signal peptides and GPI anchor sites. These genes, which appear to be evolving very quickly, are not found in either *Leishmania major* or *T. cruzi*, indicating that they are specific to African trypanosomes.

A source of variation with potentially important functional consequences is allelic polymorphism. We detected high-confidence SNPs and fixed differences by mapping the *T. b. gambiense* reads to the *T. brucei* 927 reference sequence. Our analysis focused on the non-repetitive component of the genome as firstly, non-identical repeats can appear indistinguishable from SNPs and secondly, repeated regions may be subject to unusual selective pressures (see below). After excluding these sequences, we identified a total of 224,568 putative fixed differences from 19.4 Mb of non-repetitive sequence, i.e. a diversity (π) of 0.0116 nucleotides per site. 92,794 of these differences were in coding regions, 49% of which were non-synonymous. To confirm that the variation identified when mapping the *T. b. gambiense* reads against the *T. b. brucei* 927 were not in fact false-positives due to heterozygosity within the *T. b. brucei* 927 reference sequence itself we also used the available capillary read data from the *T. b. brucei* 927 genome project to identify polymorphism within the published ''haploid'' consensus. Unfortunately, this was only possible for the four chromosomes (1, 9–11) that were originally produced by shotgun sequencing, (rather than a clone walking strategy), since these contain data from two homologous chromosomes at a given locus. From the SSAHA alignments, we identified 23,804 SNPs in 10.8 Mb of map-able sequence ($\pi = 0.0022$), of which 1,187 had the same heterozygous alleles in both the *T. b. brucei* 927 and the *T. b. gambiense* genome, indicating a false-positive rate of 5%. We identified 298 regions exhibiting higher than average diversity along the megabase chromosome. It is noteworthy, that this analysis excluded all telomere proximal regions owing to their highly repetitive nature. Whereas telomeres are well established in many species as sites of sequence variation and rearrangement [39–40], the presence of interstitial regions of high diversity in addition to the sub-telomeres is striking.

Disruptions to chromosomal colinearity are rare and reveal few subspecies-specific features

On rare occasions the otherwise consistent chromosomal colinearity is disrupted by sequence inversions and insertion-deletion events (indels). In many cases indels coincided with sequence gaps, making it difficult to confirm genuine rearrangements. Nevertheless, chromosome 10 provides two examples,

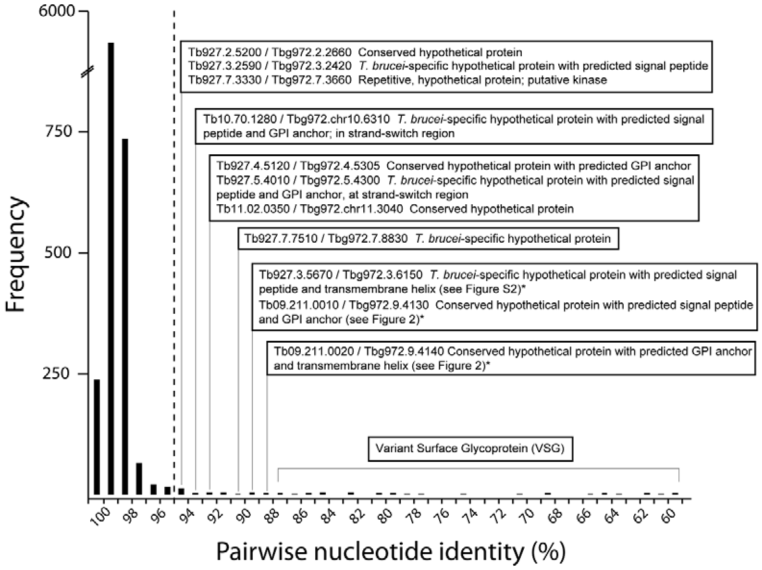

Figure 1. Frequency distribution of pairwise sequence divergence between 6929 single-copy gene orthologs in *T. b. brucei* and *T. b. gambiense*. Divergence values to the right of the dashed line are statistically significant; the identities of selected divergent gene pairs are noted. An asterisk * denotes genes belonging to a *T. b. brucei* subspecies-specific tandem gene array (see Figure 2 and Supplementary Figure S2).
doi:10.1371/journal.pntd.0000658.g001

between 275–330 kb and 3250–3350 kb, of 55 and 110 kb segmental inversions respectively. Gene order within these inverted regions remains conserved. Typically, indels have two principal causes: transposable elements and internal *VSG* 'islands'. Transposable elements such as *ingi* and RIME sequences recombine in trypanosome genomes and are responsible for several rearrangements [27]. On chromosome 9, a 7 kb insertion occurs in *T. b. brucei* due to an *ingi* element (at 1.24 Mb) not present in *T. b. gambiense*. Similarly, a 29 kb indel follows Tb11.02.5830 where an expression site-associated gene (ESAG) and a trans-sialidase gene have been inserted into *T. b. gambiense* at the corresponding position to a RIME sequence in *T. b. brucei*. By their nature, such rearrangements frequently occur in repetitive regions of the genome and, consequently, are difficult to resolve in genome assemblies. This therefore does not preclude that further events will be identified in the future.

Another source of genomic variation concerns core chromosomal *VSG* and *ESAG* genes. *VSG* genes are predominantly found in subtelomeric arrays, on intermediate or mini-chromosomes [27,13]. In addition, *VSG/ESAG* genes are less commonly found non-telomerically as 'islands', often on the opposing strand to neighbouring loci. These genes (or pseudogenes) may be: (i) atypical VSGs that do not encode all elements for accurate folding or post-translational modification; (ii) *VR* genes; or (iii) canonical *VSG* genes, imported from the subtelomere or mini-chromosome through segmental duplication. An example of the latter is a segmental insertion including 8 *VSG* genes that affects chromosome 9 in *T. b. gambiense* (Tbg972.2.570–640), since the *VSG* sequences are unrelated to each other and therefore, have not resulted from recent tandem duplications. In total, 17 such *VSG/ESAG* islands were noted in both genomes, only 6 of which were unique to one subspecies or other, including a segmental duplication in *T. b. brucei* of an atypical *VSG* combined with an insertion or deletion of *ESAG*s (Supplementary Fig. S1). Clearly, *VSG/ESAG* islands are among the more dynamic features of core chromosomes, yet where they are conserved between *T. b. brucei* and *T. b. gambiense* they contain orthologous gene sequences, indicating that they not exposed to frequent gene conversion processes like *VSG*s elsewhere.

Beyond transposable elements and *VSG* 'islands', other differences in gene order are caused by a class of small, putative coding sequences of unknown function (103 cases). These genes encode hypothetical proteins with a predicted length of 151–274 amino acids and which have no database matches to any experimentally characterized protein. Transcriptomic data (George Cross, Rockefeller University, unpublished data; Veitch et al., University of Glasgow, submitted) suggest that some of these putative genes are at least transcribed, although no product has yet been identified in proteomic assays to date (Aswini Panigrahi, SBRI, pers. comm.). Regardless of which genome encodes the putative gene, homologous sequences of high identity are found in the other genome at the corresponding positions, but without the open reading frame. Hence, they may be non-coding RNA genes or other non-coding conserved elements of undiscovered function. These features are annotated to ensure completeness, and they may yet reveal functional importance, but our view is that they are unlikely to produce proteins and will not be considered further.

An isolate-specific locus: a putative iron-ascorbate oxidoreductase in *T. b. brucei* 927

Our comparative analysis identified only a single coding sequence, a putative iron-ascorbate oxidoreductase (Tb09.211.4990), which is absent from the genomic repertoire of *T. b. gambiense*. We did not identify the *TgsGP* locus, which is known to be unique to *T. b. gambiense* [24] because it is located in the subtelomere and these regions were not fully assembled. However, sequence identical to *TgsGP* was identified among the unassembled reads. Thus, it is possible that other subspecies-specific genes exist within the subtelomeres that are not recorded here. Tb09.211.4990 is preceded upstream on chromosome 9 by a strand-switch region and downstream by both retrotransposon-like proteins and the splice-leader RNA tandem array. This region is conserved in *T. b. gambiense*, but the oxidoreductase is absent. The gene is absent from the more distantly related kinetoplastids *Leishmania major* and *T. cruzi*, as well as 9 out of 11 other *T. b. brucei* strains and a representative group 2 *T. b. gambiense* (STIB 386) that we examined with PCR primers specific to this oxidoreductase (data not shown). When compared phylogenetically with other iron-ascorbate oxidoreductases in *T. brucei*, (principally the tandem gene array at the right-hand terminus of chromosome 2, e.g. Tb927.2.6180), this protein is clearly structurally distinct (only 80% amino acid identity) and constitutes an evolutionarily old lineage. This suggests that Tb09.211.4990 is gained and lost at the population level, and that it provides additional functionality to *T. b. brucei* 927 and two other *T. b. brucei* strains in which it has been found.

Segmental duplications of putative membrane proteins contain subspecies-specific gene copies

The comparison of gene content did not identify widespread subspecies-specific loci, and found no obvious differences that could explain the distinct phenotypes of *T. brucei* subspecies. For example, ornithine decarboxylase, the target of eflornithine to which *T. b. gambiense* is uniquely sensitive, is present in single, diploid copy in both genomes and displays only a single non-synonymous substitution (N137I). We did, however, detect substantial variation within families of certain uncharacterized genes that could have important functional consequences. Such differences in co-linearity involve either the expansion of a single-copy gene in one subspecies to a tandem pair in the other, or a difference in the number of duplicates where there is a tandem array in both subspecies. Current methods of genome assembly tend to detect the first scenario (i.e., single copy vs. many) but have limitations in accurately quantifying copy number and in distinguishing between copy number and allelic variation. In fact, while the *number* of repeat units assembled can be arbitrary, the *variation* among tandem gene duplicates can be accurately assessed from genome sequence data for the two subspecies. In 20 cases, a single-copy feature (be it a single gene or chromosomal segment) in *T. b. gambiense* exists in multiple, tandem copies in *T. b. brucei*, while 8 cases of the converse were observed (Table 1). For the majority of these cases, the tandem duplicates were identical and the duplication did not result in any novel, unique sequence. But in 8 cases in *T. b. brucei*, the extra duplicates contained sequence variation that might represent subspecies-specific isoforms. In four additional cases, the would-be unique sequences were found among sequence reads of the apparently single-copy subspecies, indicating that it had been omitted from the assembly (marked by an asterisk in Table 1).

The genes involved in these *T. b. brucei*-specific segmental duplications are as yet uncharacterized, but their features suggest that they are potential sources of subspecies-specific factors and interesting opportunities for further research. They are evolutionarily novel since they are not conserved in either *T. cruzi* or *L. major*; several encode proteins with predicted cell surface roles; and some are among the fastest evolving of all *T. brucei* genes. For example, a tandem gene array of hypothetical genes encoding

cysteine-rich secretory proteins is shown in Supplementary Fig. S2; these are homologous to a single gene (Tbg972.3.6170) at the corresponding position on chromosome 3 in *T. b. gambiense*. From the relative strength of BLAST hits between homologs, it is clear that the first gene in the array and the singleton in *T. b. gambiense* are orthologs, while the additional copies in *T. b. brucei* (absent

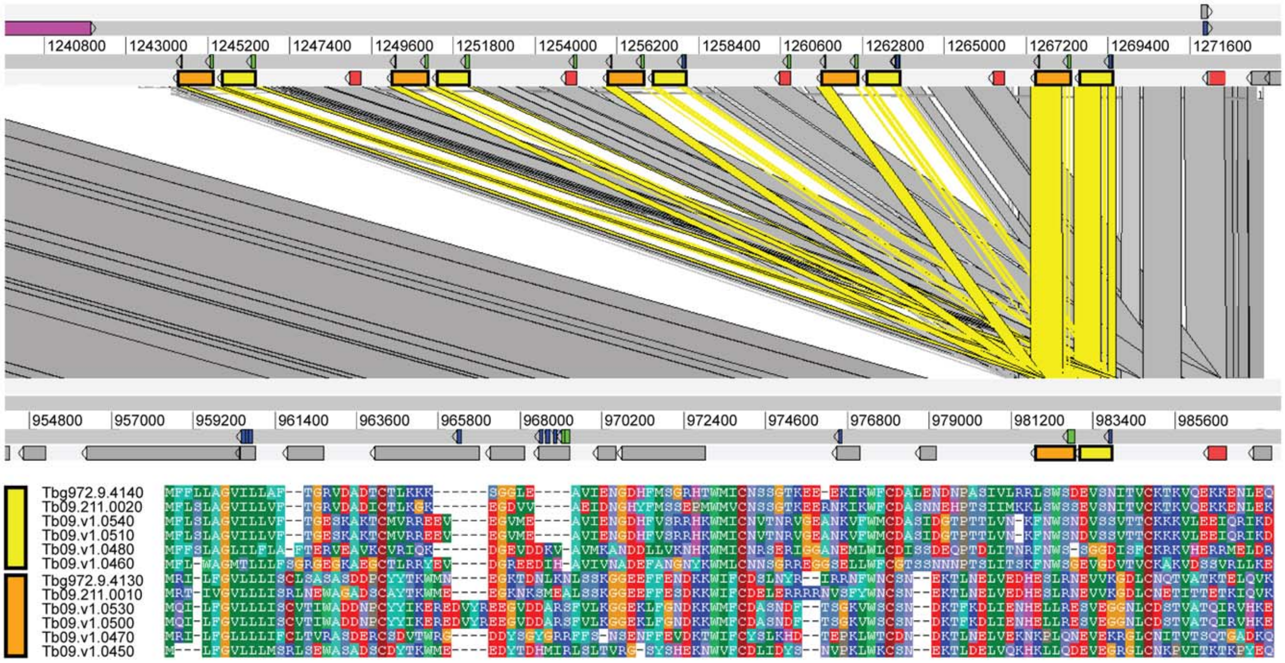

Figure 2. Segmental duplication on chromosome 9 in *T. b. brucei*. A single segment in *T. b. gambiense* comprising three coding sequences (Tbg972.9.4160, 4140 and 4130) corresponds to a three-gene segmental duplication (5 repeats) on chromosome 9 in *T. b. brucei*. The first coding sequence (shaded red) is a conserved, hypothetical gene encoding a putative secretory protein and all copies are identical. The second (shaded yellow) and third (shaded orange) coding sequences are tandem-duplicate, conserved hypothetical genes encoding putative membrane-bound proteins. Both second and third genes contain substantial sequence variation in *T. b. brucei*; the upstream-most copies are orthologous to the *T. b. gambiense* genes, but none of the remaining variants were identified among *T. b. gambiense* sequence reads. The segmental duplication is preceded immediately upstream by an INGI-mediated insertion (shaded purple).

doi:10.1371/journal.pntd.0000658.g002

from the *T. b. gambiense* read library) are unique paralogs. Indeed, they have evolved considerably, sharing only 55.1% amino acid identity with the upstream orthologs. Similarly, Figure 2 shows a single segment on chromosome 9 in *T. b. gambiense* (Tbg972.9.4160, 4140 and 4130) that corresponds to five tandem repeats in *T. b. brucei*. Among gene duplicates of the second and third coding sequences, which encode hypothetical transmembrane and GPI-anchored proteins respectively, there is considerable sequence variation (average nucleotide identities of 51.2% and 59.1% respectively). As in Supplementary Fig. S2, the 5′-most segment in *T. b. brucei* is orthologous to the *T. b. gambiense* genes, but the downstream copies are structurally divergent. A third example of segmental duplication with subsequent divergence of tandem copies occurs on chromosome 6 and concerns a hypothetical protein with a predicted signal peptide and GPI anchor (Supplementary Fig. S3).

Such segmental duplications provide rare examples of subspecies-specific gene paralogs or isoforms. It remains to be seen how common, and how ephemeral, such copy number variation is among *T. brucei* strains generally. But these cases are especially interesting because they do not simply concern gene dosage. In fact, with divergence in protein sequence often between 30–40% among paralogs, the effects on protein function could be considerable. Not only have these genes multiplied in number in very recent evolutionary time, this has been accompanied by rapid structural divergence in their predicted cell surface gene products, suggesting a role for adaptive change. Such protein isoforms could contribute to the observed differences between group 1 *T. b. gambiense* and other *T. brucei* isolates in the host-parasite relationship, both in the mammalian and insect hosts.

Tandem gene arrays frequently contain subspecies-specific sequence mosaics

Tandem gene arrays in the *T. b. brucei* genome usually contain sequence variants and analysis of tandem duplicate variation using *T. b. brucei* sequences alone showed that divergence frequently results in sequence mosaics and concerted evolution within genomes [31]. After discounting the minority of invariant tandem arrays in *T. b. gambiense*, 35 tandem gene arrays that contained sequence variation were compared with their *T. b. brucei* homologues, demonstrating that 27 arrays contained subspecies-specific gene copies (Table 2). In 5/49 instances subspecies-specific copies displayed unique sequence motifs, suggesting differential assortment of the ancestral gene repertoire between the daughter subspecies. Elsewhere, subspecies-specific copies were recombinants of other duplicates. Tests for recombination carried out on multiple alignments of gene copies from both subspecies demonstrated that sequence mosaics occurred in 31/35 data sets as exemplified by the array of invariant surface glycoproteins on chromosome 2 (ISG; Tb927.2.3270–3320) (Fig. 3). The ISG array comprises 6 and 12 gene copies in *T. b. brucei* and *T. b. gambiense*, respectively. GARD analysis detected at least five recombination breakpoints (Fig. 3a) and the recombinant nature of ISG is reflected in a highly reticulated phylogenetic network (Fig. 3b). This also identifies potential subspecies-specific recombinants, for instance, the proximity of 'Tbg7' to 'Tbg10' reflects the overall similarity of these copies, but closer inspection shows that small sections of homology exist with other copies, i.e., 'Tbg8/9'(Fig. 3c). Similarly, the intermediate position of Tbg1 reflects its affinities with multiple, unrelated sequences (Fig. 3d).

doi:10.1371/journal.pntd.0000658.t002

Subtelomeres are compositionally similar

Some of the hardest genome regions to reliably assemble are subtelomeres, since they usually contain numerous high-copy gene families, as well as simple and complex sequence repeats. The fluidity of subtelomeric assemblies perhaps reflects some reality about the true mutability of subtelomeric regions, since they are known to vary widely in length between trypanosome strains [41]. In comparing ~1.3 Mbp of subtelomeric sequence immediately contiguous to the chromosomal cores between the two subspecies, it is clear that they are highly similar in composition and gene order. In both *T. b. brucei* and *T. b. gambiense* the largest component of subtelomeric genes comprises *VSG*s (67.8% and 44.4%, respectively), followed by *ESAG*s (13.4%, 15.8%), and transposable element-related genes (7.6%, 13.5%). Adenylate cyclases (2.2%, 3.0%) and glycosyltransferases (1.1%, 1.5%) are also prominent features in both genomes. Beyond these subtelomeric regions, previous comparisons of telomeric VSG expression sites in various *T. brucei* strains and subspecies have established that the essential components are ubiquitous [42–43]. Hence, although *T. brucei* telomeres are known to evolve rapidly and display widespread karyotypic variation, the composition of regions beyond core chromosomes remains consistent across the species.

VSG sequence types are conserved between *T. brucei* subspecies

As the relative divergence (Fig. 1) and antigenic variability of different *T. brucei* strains is of diagnostic and clinical importance, we investigated the diversity between the *VSG* repertoires in the two subspecies by comparing all of the 1258 *VSG* sequences annotated to date in the *T. b. brucei* 927 genome with the unassembled sequence reads from the *T. b. gambiense* genome. Hence, it should be noted that we are comparing whole genes from *T. b. brucei* with fragments from *T. b. gambiense*. Among *VSG* genes with reciprocal top hits in the *T. b. gambiense* read library, the average amino acid identity is 43.3%, but with substantial variation (SD = 21.35, n = 692). Clearly, the substitution rate affecting *VSG* nucleotide sequences is relatively high, due either to positive selection, or a relaxation of purifying selection. Yet *VSG*s do not evolve so quickly as to abolish detectable orthology between subspecies; 692 *VSG* genes had a reciprocal top BLAST hit with a *T. b. gambiense* sequence read, indicating that 55% of the *T. b. brucei* repertoire (or parts thereof) were conserved in *T. b. gambiense*. Furthermore, 1061 VSG genes (84%) had reciprocal BLAST hits or very close matches, (i.e., within the top three BLAST hits for the matching *T. b. gambiense* read). The network representation emphasizes the global perspective of the VSG repertoire in *T. b. brucei* 927 relative to *T. b. gambiense* (Fig. 4). 197 VSG without close matches to *T. b. gambiense* reads are distributed throughout the network, indicating that they do not share a common origin and represent losses in *T. b. gambiense*.

As the *T. b. brucei* 927 subtelomeric sequences are incomplete, its *VSG* set is partial, and therefore further *T. b. brucei*-specific *VSG* sequences may be identified in future. That said, our analysis consistently demonstrated that *VSG* genes have corresponding sequences in both subspecies, though 787 (63%) were better related to other *T. b. brucei* genes than any *T. b. gambiense* read, suggesting that a gene duplication or gene conversion event had occurred since separation of the subspecies. We sought to identify phylogenetic structure, or discernable subsets, among VSG to establish limitations on gene conversion. The structural distinction between canonical VSG and VR proteins is already established [17] and is consistent with the location of VRs outside of the subtelomeres and their lack of pseudogenes. Accordingly, the VRs cluster together (yellow shading) in the network. They contrast

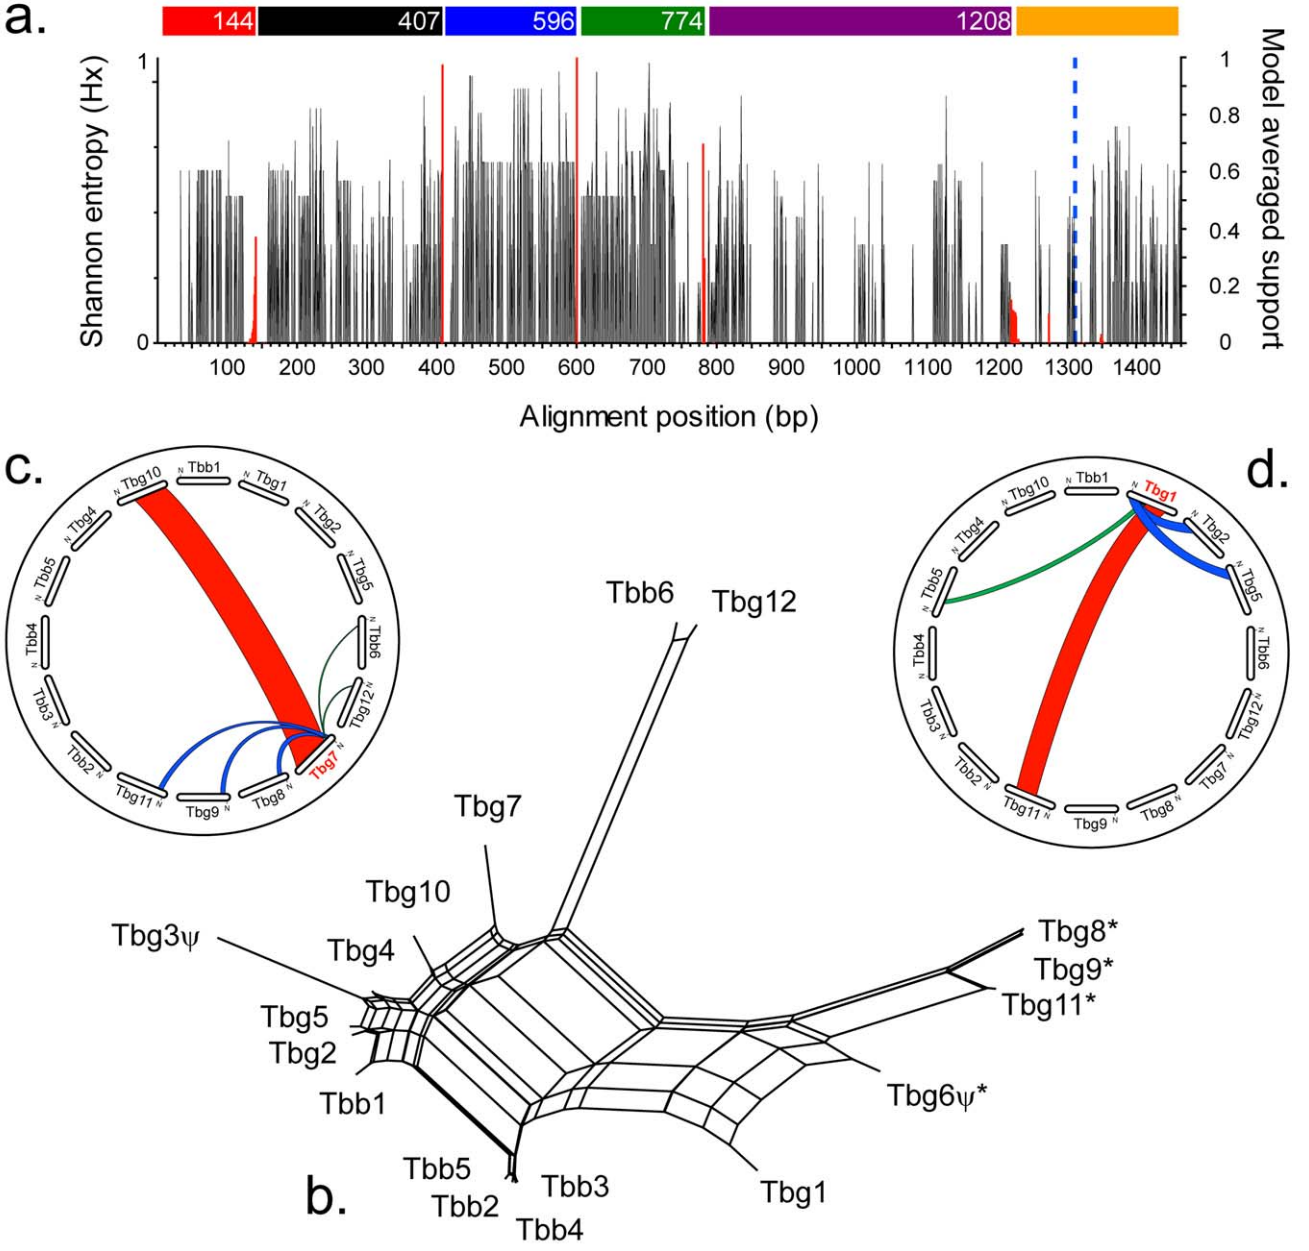

Figure 3. Analysis of sequence variation among *T. brucei* 65 kDa invariant surface glycoprotein genes. Gene copies are numbered consecutively in positional order from left to right on the chromosome, beginning with Tbb1 (Tb927.2.3270) and Tbg1 (Tbg972.2.1130) respectively. **a**. Sequence variation (expressed as Shannon entropy score, left scale) along a multiple sequence alignment, combined with recombination breakpoints (red lines, right scale) inferred by GARD analysis. A dotted blue line marks the boundary between coding and 3′ UTR regions. Coloured bars above the chart indicate recombination tracts as identified by GARD. **b**. A phylogenetic network including sequences unique to one subspecies (marked with an asterisk *). Annotated pseudogenes are indicated by ψ. **c**. A chart showing the affinities of sequence Tbg7 only; all sequences are represented in a circle, coloured bars connect Tbg7 (or regions thereof) to its closest relative among other sequences. Different colours are used to denote different affinities. **d**. Affinity chart for Tbg1.
doi:10.1371/journal.pntd.0000658.g003

with the otherwise diffuse arrangement of canonical VSG; sequences do not cluster by chromosomal location or by developmental stage expression since metacyclic-VSG are distributed throughout. VSG specific to *T. b. brucei* (red shading) do not belong to a single lineage, and equally, there is no evidence for evolutionary expansion of a particular subset. Instead, these data indicate that gene conversion has occurred frequently among subtelomeric *VSG* in the recent past, unlimited by genomic location and resulting in occasional gene loss.

The complement of variant surface glycoproteins in *T. b. gambiense* has previously been reported as being smaller, or more restricted, than that of *T. b. brucei*, based on a smaller overall genome size and reduced subtelomeric components [8]. This could indicate fewer discrete *VSG* sequence types or just fewer copies of an equal number of types. The data presented here suggest that if *T. b. gambiense* had a smaller *VSG* repertoire, this is likely to reflect quantity rather than sequence types. Hutchinson *et al.* [44] reported that, while protein sequences had diverged

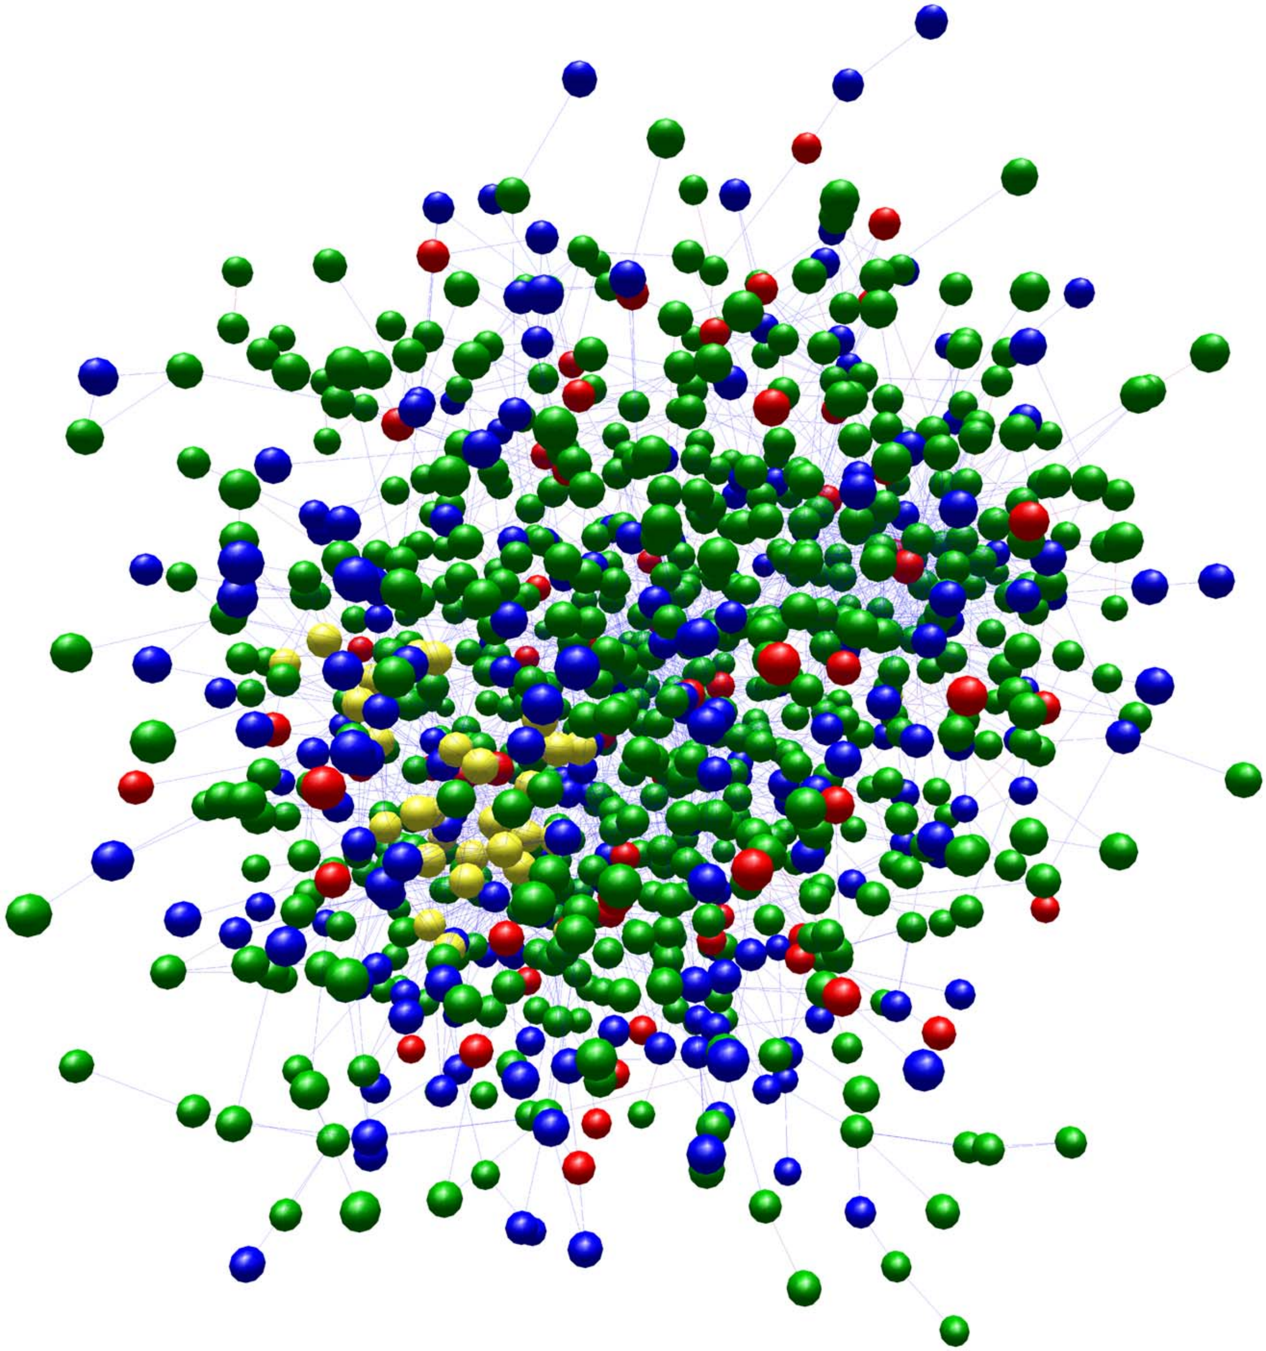

Figure 4. Variant surface glycoprotein (VSG) repertoire of *T. b. brucei* (927) represented as a three-dimensional network graph. 1258 *T. b. brucei* VSG protein sequences were compared using pairwise BLAST searches. BLAST scores were used to arrange VSG into a graph using BioLayout Express 3D 3.0. 968 individual VSG are represented as coloured spheres and are joined by edges to all other nodes with which they share >70% amino acid identity. The program minimizes the distance required to arrange all nodes such that related nodes are arranged closest to one another. Nodes are shaded by type: orthologous sequence in *T. b. gambiense* (blue), orthologous sequence in *T. b. gambiense*, but closest relative in *T. b. brucei* (green), no corresponding sequence in *T. b. gambiense* (red), metacyclic-stage VSG (purple) and VSG-related (VR) proteins (yellow).
doi:10.1371/journal.pntd.0000658.g004

consistent with subspecies-specific adaptation, 14 expressed *VSG* genes in the *T. b. brucei* Tororo strain all had close homologs in both *T. b. brucei* 927 and *T. b. gambiense*. Our data support the idea that the *VSG* repertoire is relatively stable across *T. brucei* subspecies, but that *VSG* genes have an inherently high substitution rate resulting in rapid sequence divergence relative to other genes. Corresponding *VSG* sequence types are thus likely to be found in any *T. brucei* strain, making it realistic to catalogue all *VSG* types and to monitor their expression in the field. Thus, the apparent lack of genetic hypervaribility concerning *VSG* in *T. brucei* seems simpler than other systems of antigenic variation, such as the *var* surface glycoproteins in *Plasmodium falciparum*, where frequent switching of expressed antigens is combined with genetic hypervariability and there is minimal overlap between repertoires between isolates [45–47]. Like *P. falciparum*, *T. brucei* 'shuffles its deck' with every infection, but, unlike *Plasmodium*, it always uses the same pack of cards.

Conclusion

T. b. gambiense is the most important human-infective form of *T. brucei* and currently endemic throughout central Africa. In producing a draft genome sequence for *T. b. gambiense* this study attempted to identify genetic causes for human infectivity in *T. b. gambiense*, as well as assess the scale of intraspecific genomic variation. Genomic conservation between *T. b. gambiense* and the *T. b. brucei* validates the use of *T. brucei brucei* as a model for studying the unculturable *T. b. gambiense*. Specifically, intraspecific genomic divergence is typically $<1\%$ in coding regions; gene gain and loss is associated with rare segmental duplications; indels are few and generally caused by transposable elements or *VSG/ESAG* 'islands'; and 84% of surface antigens are represented whole or in part in both subspecies. The VSG repertoire is essentially conserved at the level of modular protein domains, which are reorganized by gene conversion into novel mosaics in each strain. Therefore our data are likely to anticipate the archive present in the genomes of other strains, and a definition of total VSG diversity should be achievable through the addition of further sequences in the near future.

Comparative genomics has identified species-specific genes in other eukaryotic pathogens that display interspecific pathological variations, including *Leishmania* spp. [48]; *Candida albicans* and *C. dubliniensis* [49]; and *Plasmodium knowlesi* and *P. vivax* [50]. In applying a similar rationale here, we found no obvious candidate for a gene analogous to *SRA* that could account for human-infectivity in *T. b. gambiense*. However, since both *SRA* and *TgsGP* are homologous to *VSG* genes and subtelomeric, such a gene might not be apparent from comparison of the core chromosomes and could still exist within the subtelomeres of *T. b. gambiense*. Alternatively, rather than differences in gene content *per se*, phenotypic variability could be due to individual SNPs or indels, or to differences in gene expression. Given that innate immunity to trypanosomes in Humans is based on the uptake of high-density lipoprotein particles, which contain apoL1 and stimulate trypanolysis [20–21], perhaps the likeliest cause of phenotypic variation relates to this process. Indeed, it is possible to select for resistance to trypanolysis by down-regulating *TbHpHbR* [51], which encodes an haptoglobin-haemoglobin surface receptor that normally scavenges haem from the host, but also facilitates the uptake of trypanolytic particles [52]. However, this gene is present in *T. b. gambiense* (Tbg972.6.120) and differs from its *T. b. brucei* counterpart (Tb927.6.440) by only 5 amino acid replacements (L210S, A293V, E369G, G370A and M398I).

Hence, the basis for human infectivity in *T. b. gambiense* remains debatable, and we must now consider that features shared by both subspecies have been modified in structure or expression in *T. b. gambiense* to provide the genotypic basis for resistance to trypanolysis. This issue apart, several putative cell-surface protein families that include subspecies-specific members have been identified in *T. b. brucei*. These proteins are previously unrecognized elements of the trypanosome surface that display both recent gene duplications and accelerated evolutionary rates and we speculate that they may have acquired novel functions. We also suggest the presence or absence of such hypothetical genes varies on a population scale, and might yet contribute to phenotypic variability in host range within *T. brucei*.

Abstract

The genetic architecture of blood pressure now comprises over 30 genes with rare mutations resulting in inherited forms of hypertension or hypotension and 1477 common single nucleotide polymorphisms (SNPs) associated with blood pressure. Monogenic syndromes predominantly involve the renin-angiotensin-aldosterone system, the adrenal glucocorticoid pathway and a smaller fraction due to neuroendocrine tumours of the sympathetic and parasympathetic system. The discovery of somatic mutations causing aldosterone producing adrenal adenomas revealed the critical role of calcium signalling in adrenal aldosterone synthesis. The per-SNP BP effect is small for SNPs from genome wide association studies and all the BP GWAS SNPs explain about 27% of the 30-50% estimated heritability of blood pressure. Whilst there is a paucity of GWAS SNPs mapped to known monogenic genes, a GWAS signal mapped to the uromodulin gene has been shown to affect blood pressure through sodium homeostasis, while another appears to act through endothelin. Majority of the SNPs show pleiotropic associations and unravelling these signals have the potential to understand underpinning biological pathways. In this review, we look at the current state of blood pressure genomics and explore causal pathways from mendelian randomisation studies and opportunities for drug repurposing and pharmacogenomics.

Hypertension; blood pressure; monogenic; repurposing; pharmacogenomics; salt; adrenal; sympathetic system

Introduction

Blood pressure is the pressure exerted by blood on walls of the arteries and is critical to the maintenance of oxygen and nutrient delivery and cardiovascular homeostasis.[1] Physiological regulatory mechanisms maintain blood pressure within a 'normal range' with lower and higher values beyond this range resulting in deleterious consequences – ischemia, myocardial infarction, stroke, kidney disease.[2] Blood pressure is normally distributed in the general population exhibiting a log-linear incremental risk of cardiovascular disease with every 1 mmHg rise in blood pressure.[3] The transition from 'normal' blood pressure to hypertension is currently based on an absolute blood pressure value (that has progressively moved downwards over the last 50 years[2,4]) at the upper end of the distribution of BP "at which the benefits of action (i.e., therapeutic intervention) exceed those of inaction".[5] Hypertension is recognised as the leading modifiable risk factor responsible for the global burden of cardiovascular disease and disability with an estimated 1.5 billion people are affected, and 10.7 million deaths (33.2% of deaths due to all risk factors) in 2015 directly attributable to a systolic BP >140 mm Hg.[6]

Though blood pressure can be parsimoniously defined as the product of cardiac output and peripheral arterial resistance, these two parameters are in turn regulated by a complex network of renal, neural, cardiac, vascular, and endocrine mechanisms under the influence of genetic and environmental factors (Figure 1). Thus, blood pressure is a multifactorial polygenic trait and by extension, hypertension, which is a dichotomisation of the quantitative blood pressure trait is likewise a multifactorial complex trait. This has been aptly illustrated in the 1960's Page model of hypertension and updated in 2014.[7,8] Systolic blood pressure shows a linear age related rise suggesting that increasing blood pressure incites vascular injury or dysfunction, which in turn leads to a vicious cycle of accumulating vascular injury and higher blood pressures.[9] The age-related rise in blood pressure is observed only in industrialised societies and not in non-westernised-tribal populations where routine dietary salt intake and other environmental stressors and exposures that increase BP are absent.[10,11] While there are clear environmental and occupational factors in addition to salt intake that influence risk of hypertension,[12] there is now accruing evidence for considerable genetic contribution from monogenic syndromes of high and low blood pressure and the exponential rate of identification of validated blood pressure single nucleotide polymorphisms (SNPs) from genome wide association studies (GWAS).[13-15] The causal genetic mutations have been established as necessary and sufficient to cause the blood pressure phenotypes in monogenic syndromes. In contrast, GWAS SNPs may provide the necessary conditions but, by themselves, do not provide sufficient cause for the manifestation of the blood pressure phenotype. In this review, we provide a broad perspective on how genomics has transformed our understanding of blood pressure and hypertension and provide a context for the opportunities and challenges for their full clinical potential to be realised. A detailed description of all the genetic variants and molecular mechanisms is not provided as these areas have been reviewed recently.[13]

Genetic contribution to blood pressure and hypertension

There is now substantial support from multiple lines of observational evidence that indicate genetics play a non-trivial role in the regulation of blood pressure. These are summarised below.

- Family and twin studies indicate a substantial heritable component for blood pressure with heritabilities ranging from 15% to 40% for clinic systolic blood pressure(SBP), and 15% to 30% for clinic diastolic blood pressure (DBP), 69% and 51% for ambulatory SBP and DBP respectively.[16,17] Heritability is a property of the population studied and whilst most of the estimates are obtained from European populations, there is data from African ancestry individuals showing similar levels of heritability.[18]
- Monozygotic twins show a greater correlation of blood pressure compared to dizygotic twins.[19] Family studies have shown risk of hypertension in an individual increases in the presence of parental and grandparental history of hypertension.[20] The familial risk of hypertension is likely to be due to genetic factors after statistical modelling showed that hypertension in grandchildren from grandparents persisted after adjustment for secular

trends, inter-generational differences in lifestyle and behaviour, physical activity and dietary sodium intake.[20]

- The existence of rare monogenic forms of high and low blood pressure with the identification of their underlying causal mutations indicates the role of specific genetic pathways primarily centred in the kidneys and adrenal glands to have a major impact on blood pressure.[13]
- The burst of discoveries in the genome wide era has unequivocally established the polygenic component in the genetic architecture of blood pressure.[14]
- Genetically determined systolic blood pressure based on 12 polymorphisms associated with blood pressure from genome wide association studies was shown to be causally associated with the age-related rise in systolic blood pressure.[21] This supports the hypothesis that increased SBP (inferred from genetic risk alleles) causes vascular injury, which in turn leads to higher SBP longitudinally.

Genetic architecture of hypertension

The genetic architecture of a trait encompasses all genetic factors and their characteristics involved in the expression of the phenotype, and is important for screening for and diagnosing disease as well as enhancing biological understanding, drug development and gene mapping.[22] It comprises the number of variants influencing a phenotype, the magnitude of their effects on the phenotype, the population frequency of these variants and their interactions with each other and the environment. Figure 2 depicts the current genetic architecture of blood pressure including 31 different genes harbouring rare causal variants for monogenic syndromes of high and low blood pressure and over 1477 common SNPs associated with blood pressure traits from GWAS.[13-15] The preponderance of common over rare variants is a reflection of the late onset nature of hypertension making it less susceptible to purifying selection. The multifactorial nature of blood pressure regulation was exemplified by the Page mosaic theory of hypertension[7] of 1960 which posited that essential hypertension (HTN) is not one disease, but several different diseases with different origins and development which included interactions among genetics, environment, adaptive, neural, mechanical, and hormonal perturbations (sympathetic nervous system, renin-angiotensin-aldosterone system). The increasing availability of large prospective population-based cohorts has enabled genetic association studies to be conducted across a wide range of phenotypes- phenome-wide association studies (PheWAS) revealing pervasive pleiotropy of a majority of the BP SNPs. The transition from the original Page's mosaic model (a wireframe model depicting the multifactorial nature of hypertension) through an update in 2014 with results from early GWAS studies to its latest iteration in Figure 2 showcase the enormous progress that have been made in unravelling the genetic architecture of blood pressure, the eclipsing of monogenic traits by polygenic signals and the scale of integrating evidence from pleiotropic associations with other phenotypes including lifestyle and environmental influences.

Monogenic syndromes

The monogenic blood pressure syndromes all present with the same BP phenotype, but are essentially separate diseases differentiated by additional clinical or laboratory characteristics and the causative genetic mutation. Molecular and clinical details of monogenic syndromes have been reviewed in detail recently and we refer to the reader to these articles.[13,23] The details of pathways and genes involved in monogenic hypertension are presented in Figure 1 and Table 1.The monogenic variants tend to have large effects on blood pressure, around 20-50 mmHg and while not contributing significantly to the public health burden of hypertension, their value lies in helping understand the blood pressure regulatory pathways that they have uncovered. An interesting theory invoking herterozygote advantage to indicate a role for rare variations in hypertension came from a study of pathogenic alleles in SLC12A1, KCNJ1, and SLC12A3 associated with a reduction blood pressure reduced risk of hypertension in the Framingham heart study, though this is yet to be validated.[24]

The mechanisms of salt-sensitive hypertension mediated through aldosterone was elucidated through the mutations causing glucocorticoid-remediable aldosteronism, Liddle syndrome, congenital adrenal hyperplasia (deficiencies of steroid 11β-hydroxylase or 17α-hydroxylase) and apparent mineralocorticoid excess which are all characterised by low plasma renin activity, hypokalaemia, and a degree of metabolic alkalosis.[25,26] About 40% of patients with adrenal aldosterone-producing adenoma (APA) have somatic gain-of-function mutations in Potassium Inwardly Rectifying Channel Subfamily J Member 5 (*KCNJ5)* gene.[23] Around 7% of APAs are due to somatic mutations in ATPase Na+/K+ Transporting Subunit Alpha 1 (*ATP1A1)*, ATPase Plasma Membrane Ca2+ Transporting 3 (*ATP2B3)*, Calcium Voltage-Gated Channel Subunit Alpha1 D (*CACNA1D)* and Catenin Beta 1 (*CTNNB1)*.[23] Mutations in these genes are less frequent in inherited cases of primary hyperaldosteronism and this raises the possibility that HTN could be due to a multiplicity of uncommon variants.[23] The mutations in *KCNJ5, CACNA1D, ATP1A1* and *ATP2B3* highlight the crucial role of calcium signalling in autonomous adrenal aldosterone production.[27] The mechanisms underlying *CTNNB1*-mediated APA formation have not been elucidated yet.[28]

Mutations in transporters in different segments of the nephron have enhanced our understanding of sodium and electrolyte regulatory mechanisms in the kidney and their impact on blood pressure. The role of the distal convoluted tubule (DCT) in blood pressure regulation was clarified through dissection of Gordon Syndrome (pseudohypoaldosteronism type II) which causes hyperkalaemic hypertension with mild metabolic acidosis. The major sodium transporter in the DCT is Na^+/Cl^+ ion cotransporter (NCC). Gordon Syndrome is caused by mutations in two serine-threonine kinase (With No Lysine Kinase 1 and 4, *WNK1* and *WNK4*) genes, which inhibit NCC expression and sodium flux. Additionally, mutations in Cullin-3 (*CUL3*) and Kelch3 (*KLHL3*) which are involved in the ubiquitination and degradation of WNK kinases also cause Gordon syndrome. Gitelman and Bartter syndromes are forms of salt losing tubulopathies characterized by hypokalaemic alkalosis with normal to low blood pressure due to dysfunctional transepithelial electrolyte transport in the thick ascending limb of loop of Henle's loop (TAL), the distal convoluted tubule (DCT disorders), or both.[29] Classical Bartter syndrome Type I and II are due to mutations in Solute Carrier Family 12 Member 1 (*SLC12A1)* and Potassium Inwardly Rectifying Channel Subfamily J Member 1 (*KCNJ1)* genes encoding respectively the $Na^+/K^+/2Cl^-$ cotransporter 2 (NKCC2) and the renal outer medullary potassium channel (ROMK) in the TAL, while Bartter Type III and V are DCT disorders due to mutations in the chloride channel ClC-Kb (*CLCNKB*) and calcium sensing receptor (CASR) respectively. Bartter syndrome with sensorineural deafness is a combined TAL and DCT disorder due to genetic defects of chloride channels ClC-Ka (*CLCNKA*) and *CLCNKB*, and the beta-subunit of barttin (*BSND*). Antenatal Bartter syndrome is a severe form manifesting in utero with foetal polyuria and hydramnios due to mutations in *SLC12A1* and *KCNJ1* genes (NKCC2 and ROMK).[29] Recently a new form of Bartter syndrome (transient antenatal Bartter syndrome) due to mutations in the melanoma-associated antigen D2 (*MAGED2*) which maps to the X chromosome has been identified which is a combined TAL/DCT disorder presenting with polyhydramnios and salt wasting.[30] Autosomal hypertension with type E brachydactyly (HTNB) is a monogenic syndrome that causes hypertension through vascular mechanisms involving phosphodiesterase 3A leading to increased neointimal proliferation and remodelling of the arteries and neurovascular structures.[31] Phaeochromocytomas and paragangliomas (PCC/PGLs) are rare neuroendocrine tumours of the adrenal glands and the sympathetic and parasympathetic paraganglia that cause hypertension through catecholamine hypersecretion. PCC/PGLs are associated with 12 genetic syndromes classified into three clusters pseudohypoxic, Wnt-signaling, and kinase-signaling clusters. Each cluster has unique clinical, molecular and imaging characteristics that can be inform precision medicine.[32,33] The pseudohypoxia group comprises of tricarboxylic acid (TCA) cycle and VHL/EPAS1 -related subgroups. The tricarboxylic acid (TCA) cycle–related subgroup is due to germline mutations in succinate dehydrogenase subunits *SDHA*, *SDHB*, *SDHC*, *SDHD, SDHAF2* (*SDHx*) and fumarate hydratase (*FH*). The VHL/EPAS1-related subgroup is caused by somatic and germline mutations in Von Hippel–Lindau tumour suppressor (*VHL*) and Endothelial PAS domain protein 1(*EPAS1*) genes resulting in multiple and recurrent PGLs. The Wnt signaling group consists of somatic mutations in Cold shock domain containing E1 (*CSDE1*) and Mastermind like transcriptional coactivator 3 (*MAML3*). The kinase signalling group consists of germline or somatic mutations in Ret proto-oncogene (*RET*), Neurofibromin 1 (*NF1*), Transmembrane protein 127 (*TMEM127*), MYC-associated factor X (*MAX*), and HRas proto-oncogene, GTPase (*HRAS*). Approximately, 60% of PCC/PGLs are caused by known genetic mutations. About 10% of PCCs and 35–40% of PGLs are metastatic. The predictors of metastatic disease include size (≥5–6 cm), extra-adrenal location of the primary tumour, noradrenergic/dopaminergic biochemical phenotype, mutations of the succinate dehydrogenase A and B (*SDHA/B*) genes, tumour multiplicity/recurrence, and age at first presentation (<20 years).[34]

Polygenic hypertension

GWAS have transformed our understanding of complex traits but their clinical impact has been limited. A major limitation has been the difficulty in linking SNP to causal gene and function primarily because a most of the GWAS variants are found in intergenic or intronic regions with only ~10% located in the coding sequence.[35,36] The key aspects of blood pressure GWAS are summarised below.

(1) All the BP GWAS SNPs explain about 27% of the 30-50% estimated heritability of blood pressure and explain about 5.7% of the phenotypic variance of SBP.[14]

(2) The effect size of any SNP on blood pressure is small, approximately 1 mmHg for SBP and 0.5 mmHg for DBP;

(3) GWAS SNPs are tag-SNPs, which means they are likely not causal SNPs, but correlate with the functional variant elsewhere.

(4) Majority of the BP loci are likely to be in novel genes and in blood pressure GWAS with a lower likelihood of identifying signals among known monogenic genes.

(5) Majority of the SNPs identified in GWAS are common with allele frequencies >1% in the population.

(6) The GWAS signals are predominantly from studies of European ancestry subjects with other ancestries under-represented and limiting the generalisability of the findings.

(7) GWAS SNP arrays do not capture rare variants and structural variations in the genome. Information is also limited from regions of low linkage disequilibrium in the genome.

(8) The utility of incorporating all variants into a genetic risk score (GRS) for individual risk prediction is still not established and there is a potential for miss-estimation of risks in non-European ancestries.[37] A one-standard deviation increase in GRS score was associated with a 3.9, 2.4 and 2.6 mmHg increase in SBP respectively among European, African and South-Asian descent individuals in the UK BioBank;[14]

(9) Large scale collaborations using whole genome sequencing in multi-ethnic populations such as Trans-Omics for Precision Medicine (https://www.nhlbi.nih.gov/science/trans-

omics-precision-medicine-topmed-program) are designed to fill the gaps in knowledge base of genomic and other omic markers of hypertension and cardiovascular disease with a view to accelerating precision medicine.

Novel pathways from GWAS

A 5'-promoter SNP, rs13333226, near the uromodulin gene (*UMOD*) was discovered from a GWAS of blood pressure extremes.[38] This SNP affects urinary uromodulin levels the product of *UMOD* which exclusively expressed in the thick ascending limb of the loop of Henle (TAL) in the kidney where 25% of the filtered sodium is reabsorbed. Uromodulin knock-out mice have low blood pressure, absent urinary uromodulin and absent salt-induced rise in BP (shift to the left of the pressure-natriuresis curve).[39] This has identified a novel pathway of blood pressure and renal function regulation through possible interaction with the Na^+-K^+-$2Cl^-$ cotransporter (NKCC2) in the TAL. NKCC2 is blocked by the commonly used loop-diuretic furosemide, which was shown by Trudu et al[40] to significantly enhance natriuresis and reduce BP levels both in the transgenic mice and in the hypertensive individuals homozygous for the UMOD increasing allele. This is now the basis of a clinical trial (www.clinicaltrials.gov NCT03354897) to reposition a loop diuretic in the hypertension care pathway. Three SNPs from BP GWAS are related to the endothelin pathway – rs9349379 (*PHACTR1*), rs1630736 (*EDN1*), rs10305838 (*EDNRA*). The minor allele of the intronic SNP, rs9349379, in the phosphatase and actin regulatory protein 1 (*PHACTR1*) gene associated with increased risk of coronary artery disease but decreased risk of migraine, cervical artery dissection, fibromuscular dysplasia, and hypertension. This SNP subsequently has been shown to be a distal regulator of *EDN1* expression.[41,42] Endothelin 1 (ET-1) is the most abundant endothelin isoform which acts in a paracrine manner on vascular smooth muscle cells (VSMC) to produce its potent vasoconstrictor effect mediated via ET subtype A (ET_A) and ET subtype B (ET_B) receptors.[43] Endothelin receptor antagonists have demonstrated a blood pressure lowering effect but did not gain traction as an antihypertensive agent because of side-effects or failure to meet clinical trial primary end-points.[43,44] There is encouraging data from phase II study with aprocitentan, a dual ET_A/ET_B endothelin receptor antagonist,[45] and this has now progressed to a phase III trial, the PRECISION study (www.clinicaltrials.gov NCT02603809). There is also evidence that endothelins play a role in non-obstructive CAD[46] and a genotype directed trial using zibotentan is currently underway (www.clinicaltrials.gov NCT04097314). Other potential targets identified include *NPR3* (natriuretic peptide receptor C) affecting blood pressure through increased vascular smooth muscle cell proliferation, angiotensin II-induced calcium flux and contraction;[47] Two other loci that are of interest include the Sodium Bicarbonate Cotransporter, Member 7 (*SLC4A7)* and Solute Carrier Family 39 (Zinc Transporter), Member 8 (*SLC39A8)* loci.[48,49] The *SLC39A8* locus is associated with an Ala391Thr variation where blood pressure increasing Ala391 variant is associated with increased ERK2 phosphorylation, NFkB activation, cadmium accumulation and reduced vascular endothelial cell viability.[49]

Polygenic risk scores

As the genetic make-up of an individual is largely stable from birth, genetic information has the potential to act as an early risk predictor. Essential HTN is influenced by multiple genetic variants with small individual effect sizes, so meaningful risk prediction necessitates examining the aggregated impact of these multiple variants through calculation of a single metric that represents an individual's overall genetic risk. Initially this was calculated as a simple genetic risk score (GRS) which is a simple additive count of the number of risk alleles (usually from a few SNPs from GWAS, sometimes weighted by effect sizes) carried by each individual.[50] More recently, with the recognition that SNPs that do not meet highly stringent significance thresholds for genome-wide association could also be predictive of disease, a broader range of SNPs, ranging from thousands to millions have been used to generate an enhanced GRS termed polygenic risk score (PRS).[51] It is important to highlight that the risk information provided by the PRS is a probabilistic range and this is different from the risk information from genetic markers of monogenic disorders, which is dichotomous (either high or low probability of disease). Additionally, the rare variant genotype points to specific biological impact of the variant while the PRS is an amalgamation of numerous small-effect variants across the genome with no specific pathway implicated. A PRS constructed using all significant BP GWAS SNPs showed a significant association with stroke, coronary artery disease, heart failure, and left ventricular mass but not with renal function.[21,52] Compared to the bottom 20% of the GRS distribution, the top 20% was associated with a 35-40% increased risk of cardiovascular disease, MI and stroke.[14] The estimated odds ratio for a 5 mmHg increase in SBP on the risk of coronary artery disease is around 1.30[1.18–1.44] supporting the hypothesis that SBP is causally related to coronary artery disease risk. This aligns with evidence from meta-analysis of clinical trials which show every 10 mm Hg reduction in systolic blood pressure significantly reduced the risk of major cardiovascular disease events by 17%-27%.[53] Lifelong genetic exposure to lower systolic blood pressure using blood pressure GWAS SNPs as genetic instruments showed participants with SBP genetic scores higher than the median had 2.9-mm Hg lower SBP and an OR of 0.82 for major coronary events (95% CI, 0.79-0.85, $P < .001$).[54] Indeed, this mendelian randomisation study confirms the independent associations of LDL-C and SBP in a dose-dependent log-linear manner with the risk of cardiovascular disease.[54] The lack of association between blood pressure PRS and renal function also suggests that progression of renal damage due to HTN may continue despite control of HTN. Whilst there is considerable interest in the use of PRS as a biomarker for early intervention or preventive strategies, this depends on its ability to motivate healthy behaviour changes for which evidence is not consistent.[55-57] A recent study from the UK BioBank showed that adherence to a healthy lifestyle (including healthy diet, limited alcohol consumption, low urinary sodium excretion, low body mass index, and increased physical activity) was associated with lower blood pressure regardless of the underlying blood pressure genetic risk suggesting that genetically predetermined rise in blood pressure and its complications can be offset at least to some extent by healthy lifestyle.[58] Prospective randomized controlled trials are essential to translate these findings into clinical practice.

Polygenic scores have mostly been developed in exclusively or majority European populations and there are concerns about the transferability of current PRS derived from European ancestry populations to other ancestries. Preliminary data indicate that PRS can still discriminate between high and low risk groups in other ethnicities,[59] but they don't perform as well, indicating clinical uses of PRS today would systematically afford greater improvement for European-descent populations and thus exacerbate health disparities.[37] The strategies to address inequities range from recalibration of scores or variant weightings for alternative populations and establishing large GWAS projects in more diverse or non-European populations.[60,61] Until these strategies yield ancestry specific data, currently the applicability of PRS will only be possible in European ancestry populations.

Pleiotropy and causality

Phenome- wide association studies (PheWAS) are similar to a genome-wide association study (GWAS), but here each genetic variant is analysed for association with a multitude of phenotypes. PheWAS permit identification of pleiotropic SNPs and overlapping traits to identify shared pathways that may help prioritise signals for follow-up studies. We performed a look-up of all the 1477 BP SNPs in GWAS catalogue and PhenoScanner to identify all non-blood pressure traits significantly associated with these SNPs using a p-value threshold of $5x10^{-5}$.[62,63] This figure encapsulates the breadth of multi-trait associations of BP SNPs from clearly plausible correlated traits to unexpected novel traits. Surprisingly, cardiovascular complications of hypertension such as coronary artery disease, stroke and atrial fibrillation show fewer pleiotropy with BP compared to adiposity, anthropometric and haematological traits.

As genotypes are determined at conception, they are independent of environmental and life-style factors and cannot be altered by disease. This means genotype variation can be leveraged as a natural experiment to establish causal relationships between risk factors and health outcomes. This is the basis for Mendelian randomisation studies.[64] The next few paragraphs look in detail at the pleiotropic traits through the lens of published mendelian randomisation studies to determine if these pleiotropic traits have a causal role in blood pressure regulation and hypertension.

Figure 3 summarises the scale of pleiotropy of all the BP SNPs from GWAS studies. Only a minority of the over 1400 SNPs are non-pleiotropic and only 6 SNPs lie in genes known to harbour mutations for monogenic blood pressure syndromes. The highest number of pleiotropic signals are for anthropometric traits which includes height, BMI, measures of adiposity and visceral fat. Next are haematological traits which include RBC, WBC and platelet measurements. Despite the high risk of stroke with hypertension, there are only 4 BP SNPs that also associate with stroke. There are 79 SNPs which also associate with CAD, and a majority of these overlap with lipid trait associations. These pleiotropic associations require further interrogation to determine if these indicate causal relationships with blood pressure or if these associations reflect confounding or reverse causation. In this context, we now summarise various mendelian randomisation studies that have tried to shed light on these associations.

Adiposity

Epidemiological studies show a correlation between BP and BMI with each 5 kg weight reduction reducing SBP by 4 mmHg.[65] In order to establish a causal role of BMI on blood pressure, one mendelian randomisation analysis used two SNPs robustly associated with BMI (rs9939609 in the Alpha-Ketoglutarate Dependent Dioxygenase (*FTO)* and rs17782313 in the Melanocortin 4 Receptor (*MC4R)* genes) and showed a 10% elevation in genotypically determined BMI was associated with a 3 mm Hg increase in systolic BP.[66] While visceral fat is known to be a better marker of cardiovascular risk, there is data to show that higher fat mass index and BMI are similarly associated with higher blood pressure suggesting that BMI may be a useful surrogate for visceral fat.[67]

Alcohol intake

Eighteen BP SNPs show pleiotropic association with alcohol intake. Interventional trials show a strong dose-response between reduction in alcohol intake and BP reduction.[68] A causal link between alcohol intake and blood pressure level has been explored using mendelian randomisation studies employing two indicator variables - rs1229984 mutation in alcohol dehydrogenase 1 (*ADH1*) and rs1229984) and rs671 in aldehyde dehydrogenase 2 (*ALDH2*) genes. The rs1229984 variant common in Caucasians heightens *ADH1* activity leading to more rapid oxidation of alcohol to acetaldehyde, while the rs671 variant common in East Asian populations inhibits metabolism of acetaldehyde by suppressing ALDH2. A large Mendelian randomisation meta-analysis of 56 epidemiological studies with 261,991 participants of European descent using the rs1229984 variant showed lower genotype-predicted alcohol intake was associated with low SBP. Similarly a study from the China Kadoorie Biobank involving 161,498 participants and using both rs1229984 and rs671 showed SBP increased by 4·8 mmHg per 280 g/week genotype-predicted alcohol intake only in males.[69,70] The gender difference may be explained by male drinkers likely consuming more per drinking session than females. While both epidemiological and mendelian randomisation results show consistent results, a caveat need to be acknowledged that ALDH2 genotype is independently associated with blood pressure as well, independent of alcohol consumption, which renders this variant unsuitable for mendelian randomisation analysis.

Birth weight

There are 28 BP SNPs associated with birth weight out of the 65 SNPs that have been associated with birth weight in genome-wide association studies (GWAS). These results suggest that there are common biological pathways that affect infant survival and future risk of cardio-metabolic diseases in adulthood.[71] The observation that higher blood pressure in later life is associated with low birth weight has two possible explanations from a mendelian randomisation analysis. It shows that maternal BP lowering alleles are associated with lower offspring birth weight (indirect maternal effect), but the same alleles inherited by the foetus result in future higher blood pressure (direct foetal effect). Birth weight-lowering genotypes in the mother does not associate with higher offspring BP implying that the inverse birth weight-blood pressure association is due to genetic effects rather than intrauterine effects.[72]

Height

Height is a pleiotropic association with 199 BP SNPs. Several epidemiological studies have reported inverse association between adult height and blood pressure (BP). One reason for high SBP in short individuals is presumed to be due to early appearance of reflected waves during systole which combines with the forward wave leading to amplification of SBP.[73] In humans, taller height is associated with reduced risk of hypertension and CAD but increased risks of atrial fibrillation, venous thromboembolism, neoplasms.[74] 194 BP SNPs also showed significant association with height. Mendelian randomisation analyses showed a one-standard deviation higher genetically determined height (~6.5 cm) results in a 16% decreased risk of CAD[75] and a 12% decreased risk of hypertension.[74] Height and lung function are closely correlated with a large number of shared genetic loci and lung function has been shown to be the mediator of the effect of height on CAD rather than blood pressure.[75]

Heart rate

Sixty-one BP SNPs show pleiotropic association with heart rate. Observational studies show that increased heart rate is a common feature in hypertensive patients and elevated heart rate is associated with the development of hypertension.[76] Mendelian randomisation studies of SNPs showed only a minor effect of resting heart rate on.[77]

Haematological traits

Blood cells are essential for oxygen transport, haemostasis, innate and acquired immune responses, iron homeostasis, vascular and endothelial function. Observational studies show and association of associations of total white blood cell, granulocyte, and neutrophil counts and RBC traits with CHD risk.[78-84] Mendelian randomisation studies indicate that there is no causal link between red blood cell count, total white blood cell, granulocyte, and neutrophil counts with CHD risk.[85] Interestingly, there is evidence for a weak positive association of CHD risk with reticulocyte indices and the weak inverse association of CHD risk with platelet volume.[85] Reticulocyte count showed a weak direct association with CHD risk,[85] and a possible explanation for this relate to higher reticulocyte count reflecting increased haemolysis with consequent higher circulating free haemoglobin which depletes NO.[86] Furthermore, free haemoglobin in blood substitutes leads to reduced nitrous oxide, increased vasoconstriction, and a higher risk of acute myocardial ischaemia.[87] Increasing platelet volume shows a weak causal relationship with lower CHD risk,[85] in contrast to systematic reviews and observational studies,[88] warranting further investigation.

Education and socio-economic status

Socioeconomic factors such as education have been associated with cardiovascular disease, though educational opportunities are not equitably distributed in the population and interventional studies are difficult.[89] A UK BioBank mendelian randomisation study showed each additional standard deviation of education (3.6 years) was associated with a 37% lower risk of coronary heart disease, and 21% of this protective effect was mediated through systolic blood pressure with BMI and smoking mediating another 21%.[90]

Alzheimer’s disease

Inherited lifetime exposure to higher SBP is associated with lower AD risk (odds ratio [OR] per standard deviation [15.4 mm Hg] of SBP [95% CI]: 0.75 [0.62–0.91]; p = 3.4 × 10−3) and with a higher probability of taking antihypertensive medication.

Pharmacogenomics

The goal of genomics is to enable precision medicine through a greater understanding of molecular pathways that regulate BP which can inform new drug development, personalisation of treatment and ultimately leading to a new taxonomy of HTN.[91] But there are significant challenges in realising this goal. Current treatment of HTN have not seen any new drug approval for over two decades. Tailoring of therapy has not progressed beyond considering self-reported African ancestry and serum renin levels.[2,4] The burgeoning list of genomic variants associated with BP and HTN opens opportunities for expanding our understanding of hypertension, revise and update the molecular taxonomy of HTN both of which will feed into hypertension precision medicine. This statement is supported by evidence from studies that showed a 6% improvement of efficacy and safety rates in drug validation efforts.[92] We connected BP GWAS signals to DrugBank[93] and Comparative Toxicogenomics Database[94] and extracted drug-gene interaction data for the plausible genes mapped to GWAS SNPs in previous studies.[14] Strikingly, all the major antihypertensive drug classes are captured by pharmacogenetic interaction with GWAS loci. This may reflect the fact that the putative published genes associated with GWAS SNPs were selected for plausible BP effect. More interestingly, gene-drug interactions revealed a large number of drugs that affect blood pressure. Many of these drugs are licensed for other conditions and have blood pressure decrease or increase as their known side-effect or adverse effect. These raise the possibility that some of the early wins from GWAS may be repurposing or repositioning opportunities for hypertension management.

Re-purposing or ‘multi-purposing’

Drug repositioning or re-purposing is the process of discovering new indications for existing drugs and is becoming increasingly relevant in the current climate of decreasing investments in new drug development and reduced rates of new drug approvals.[95] One approach that may enhance the likelihood of success is to reposition drugs against a target that has a genetic basis. Indeed, genetic studies have identified a large number of genes whose proteins are already targeted by drugs used in clinical practice (*ESR1* for tamoxifen, *CYP19A1* for aromatase inhibitors, *HMGCR* for statins) and novel drug targets (*PCSK9*).[96,97] Although GWAS SNPs still need to be causally linked to a target gene, there are significant advances in functional genomic and computational methods to accelerate discovery. Table 2 summarises other drugs with potential repurposing potential for hypertension and their pleiotropic associations. Riociguat, a guanylate cyclase (sGC) stimulator, is currently licensed for pulmonary hypertension and it is linked to the BP GWAS hit in *GUCY1A2.* Hypotension is a common side effect reported with with Riociguat, raising the possibility of potential use in blood pressure lowering.[98] Another possibility is Nesiritide is a recombinant B-type natriuretic peptide (interacts with *NPR3*, a BP GWAS locus) which failed in a clinical trial for acute decompensated heart failure and a high incidence of hypotension reported in these patients.[99] Finally, sodium-glucose cotransporter 2 (SGLT2) inhibitors are glucose lowering agents that also lower blood pressure and molecular docking studies show the SGLT2 inhibitor canagliflozin might act as a potent dual inhibitor of *ACHE* (BP GWAS locus) and SGLT2.[100]

Table 2 shows a wide range of drugs that are commonly used for other indications raising hopes for considerably increasing the pool of drugs for repurposing. However, repositioning needs to be carefully performed to ensure that patients are not exposed to off-target effects or side-effects from the wider target range of the drugs. For example, a number of anti-depressant and anti-epileptic drugs feature in Table 2 and a majority of them have hypotension as a known side-effect. Reviewing the pharmacological targets of these drugs raises caution about repositioning these drugs for hypertension. For example, olanzapine interacts with antihypertensive BP GWAS loci (*ADRB1, MTHFR-NPPA, ADRA1A, ADRA1B*), in addition its pharmacological targets include muscarinic acetylcholine receptor (CHRM1-4), histamine receptor (HRH1), 5-hydroxytryptamine receptor, kappa- and mu-type opioid receptor, Sodium-dependent serotonin transporter, HERG human cardiac K+ channel. Topiramate is an antiepileptic which interacts with the BP GWAS loci that are also linked to calcium channel antagonists (*CACNA1C, CACNA1D, CACNB2*), but in addition its pharmacological targets include gamma-aminobutyric acid receptor, voltage-gated sodium channel, carbonic anhydrase, and glutamate receptors. These two examples highlight the potential risks of repurposing drugs for hypertension, rather we suggest that the opportunities for these drugs are in 'multi-purposing' as the increasing prevalence of multimorbidity in the population requires drugs that can treat multiple conditions. Thus, a hypothetical scenario would be for patients with epilepsy and hypertension or depression and hypertension to be considered for drugs that can benefit both. Whether this strategy will improve adherence and improve outcomes for both conditions need to be assessed through randomised controlled trials.

Conclusions

Hypertension genomics is in midst of a wealth of genomic signals but a poverty of actionable results. Follow up and clinical translation of these genetic data now looks promising with integration of pleiotropic and pharmacogenomic and functional studies. The low hanging fruits, uromodulin and endothelin SNPs that have moved on to clinical trials are harbinger of accelerated advances directly from genetics to hypertension precision medicine. Polygenic risk scores look attractive, but their clinical utility needs controlled studies and the potential ethical impacts on their widespread use exacerbating health disparities need further assessment.[37,101]

Table 1: Monogenic syndromes of blood pressure dysregulation with causal genes, key features and treatment.

Syndrome	Gene	Treatment
11β-hydroxylase deficiency	*CYP11B1*	Glucocorticoid therapy
17a-hydroxylase deficiency	*CYP17A1*	Glucocorticoid therapy, Potassium sparing diuretics
21-Hydroxylase deficiency	*CYP21A2*	Glucocorticoid therapy
3β-hydroxysteroid dehydrogenase	*HSD3B2*	Glucocorticoid therapy
Apparent Mineralocorticoid Excess (AME)	*HSD11B2*	Low sodium diet and spironolactone
Bartter syndrome	*CLCNKA* *CLCNKB* *KCNJ1* *MAGED2* *SLC12A1*	Potassium supplementation and use of cyclooxygenase inhibitors, angiotensin converting enzyme (ACE)-inhibitors and potassium sparing diuretics.
Familial Hyperaldosteronism (FH I)	*CYP11B1* *CYP11B2*	Dexamethasone
Familial Hyperaldosteronism (FH II)	Linkage to Chr 7p22, *KCNJ5*	Adrenalectomy is performed in case of APA, and medical therapy with aldosterone antagonists in case of BAH.
Gitelman syndrome	*SLC12A3* *CLCNKB*	Oral potassium and magnesium supplementation with adequate salt and water.
Hypertension and brachydactyly syndrome	*PDE3A*	Possible role for PDE3 inhibition
Hypertension exacerbation in pregnancy	*NR3C2*	Spironolactone contraindicated; sodium chloride treatment. Delivery of the foetus ameliorates hypertension
Liddle Syndrome	*SCNN1B* *SCNN1G*	Low sodium diet. Amiloride or triamteren.

Multiple endocrine neoplasia, type IIA neoplasia, type IIA	*RET*	Alpha adrenergic blockers for pheochromocytoma
Paragangliomas (PGL1-5)	*SDHA* *SDHAF2* *SDHB* *SDHC* *SDHD*	Surgery, adrenergic blockers (alpha blockade followed by beta-blockade)
Pseudohypoaldosteronism (PHA II- Gordon syndrome)	*CUL3* *KLHL3* *NR3C2* *WNK1* *WNK4*	Thiazide diuretics, prostaglandin inhibitors, alkalising agents, and potassium-binding resins. Na^+ and K^+ restricted diet
Sporadic aldosterone-producing adenoma (APA), or primary aldosteronism	*ATP1A1* *ATP2B3* *CACNA1D* *KCNJ5*	Surgery, aldosterone antagonists
von Hippel-Lindau syndrome	*VHL*	

Table 2: Pharmacologically active gene loci from genome wide association studies, their pleiotropic associations, key drug-gene interactions with their indications and blood pressure effect.

GWAS Locus	Pleiotropic Associations	Antihypertensive License	BP reduction as side effect	Effect on BP	Therapeutic context/indication
ACE	Non-pleiotropic	Angiotensin Converting Enzyme Inhibitors		↓↓↓↓	Hypertension; Heart Failure; DM Nephropathy
			Omapatrilat	↓↓	(Hypertension; Heart Failure – Failed because of ADR)
ACVR2A	Basophils, Eosinophils, Neutrophils, Renal.Function, Urate		Sotatercept	↓	(Pulmonary Hypertension – Phase II)
ADORA1	Non-pleiotropic		Adenosine	↓↓	Supraventricular tachycardias
			Pentoxifylline	↓↓	Peripheral vascular disease
ADRB1	Birth Weight		Bethanidine	↓↓	(Sympatholytic)
		Beta Blockers		↓↓↓↓	Hypertension; Angina; Arrhythmia; Heart Failure
			Dobutamine	↓↓	Inotropic support; cardiac stress testing
			Amiodarone	↓↓	Arrhythmia

AKR1A1	Basophil, Granulocytes, Height, Hematocrit, Haemoglobin, Neutrophils, Platelet traits, RBC traits, Reticulocytes, WBC		Tolrestat	↓	(Diabetes complications – Failed trials)
AKR1B10	Non-pleiotropic				(Diabetes complications – Failed trials)
BCL2	Adiposity, BMI, BMR, CAD, Glycemia, Hematocrit, RBC traits, Reticulocytes, T2DM, Visceral fat, Weight		Docetaxel	↓↓	Solid tumours
CACNA1C	Hematocrit, Hemoglobin, RBC traits		Cinnarizine	↓	Ménière's disease
		Spironolactone		↓↓↓↓	Hyperaldosteronism; Oedema; Heart Failure; Hypertension
			Drotaverine	↓↓	Antispasmodic
			Topiramate	↓	Epilepsy; Migraine
		Calcium Channel Blockers		↓↓↓↓	Angina; Hypertension
CACNA1D	Monogenic, Non- pleiotropic		Cinnarizine	↓	Ménière's disease
		Spironolactone		↓↓↓↓	Hyperaldosteronism; Oedema; Heart Failure; Hypertension
		Calcium Channel Blockers		↓↓↓↓	Angina; Hypertension

CACNB2	Non.Pleiotropic	Spironolactone		↓↓↓↓	Hyperaldosteronism; Oedema; Heart Failure; Hypertension
		Calcium Channel Blockers		↓↓↓↓	Angina; Hypertension
CHRM2	Heart Rate		Pizotifen	↓↓	Migraine
			Disopyramide	↓↓	Arrhythmia
			Cinnarizine	↓	Ménière's disease
			Acetylcholine	↓↓	
			Amitriptyline	↓↓	Depression; Neuropathic pain; Migraine
CSK	Cholesterol, Granulocytes, Hematocrit, Monocytes, Platelet.traits, RBC.traits, Renal.Function		Dasatinib	↓↓	Chronic myeloid leukaemia
CYP11B2	Height	Spironolactone		↓↓↓↓	Hyperaldosteronism; Oedema; Heart Failure; Hypertension
DBH	Non.Pleiotropic		Ascorbic acid	↓	Scurvy
DDAH1	Adiposity		Esomeprazole	↓	Peptic ulcer disease
EDNRA	CAD		Ambrisentan	↓↓	Pulmonary hypertension
ESR1	Adiposity, Height		Dobutamine	↓↓	Inotropic support; cardiac stress testing
FGR	BMI		Dasatinib	↓↓	Chronic myeloid leukaemia
FRK	Adiposity, Cholesterol, CRP, Height, LDL		Dasatinib	↓↓	Chronic myeloid leukaemia

GUCY1A2	CAD		Riociguat	↓↓	Pulmonary hypertension
HDAC7	Allergy, Asthma, Platelet.traits, Reticulocytes		Belinostat	↓	(T-cell lymphoma)
HDAC9	Adiposity, CAD, CVA				
HDAC9	Adiposity, CAD, CVA		Valproic acid	↓	Epilepsy; Bipolar Disorder; Migraine
HRH1	Adiposity, BMD, Neoplasm		Mirtazapine	↓↓	Depression
			Pizotifen	↓↓	5-HT, Muscarinic, H1, Alpha Adrenergic Antagonist
			Dimenhydrinate	↓	Vertigo
			Histamine	↓↓	
			Cinnarizine	↓	Ménière's disease
			Amitriptyline	↓↓	Depression; Neuropathic pain; Migraine
INSR	Adiposity, HDL, Height, Triglycerides, Urate, Visceral.fat		Insulin	↓	Diabetes Mellitus
KCNJ11	Adiposity, BMI, Glycemia, Height, T2DM		Diazoxide	↓↓	Hypoglycemia
LIMK1	Lung.function		Dabrafenib	↓↓	Melanoma
MTHFR-NPPB	CAD, RBC.traits, Visceral.fat	Carvedilol		↓	Hypertension; Angina; Heart Failure
NPR3	Adiposity, BMR, Height, Lung.function, Visceral.fat,		Nesiritide	↓↓	(Heart Failure – Failed clinical trial)

	Weight				
PDE10A	Non.Pleiotropic		Dipyridamole	↓↓	Adenosine deaminase and phosphodiesterase Inhibitor
			Papaverine	↓↓	(Antispasmodic)
PDE1A	Adiposity, BMR, Weight	Calcium Channel Blockers		↓↓↓↓	Angina; Hypertension
			Bepridil	↓↓	Angina(withdrawn)
PDE3A	CAD, Monogenic		Amrinone	↓	Heart Failure
PDE5A	Basophil, CAD, Granulocytes, Platelet.traits, WBC		Dipyridamole	↓↓	Antiplatelet
			Pentoxifylline	↓↓	Peripheral vascular disease
SCN10A	Heart.Rate, Neoplasm		Tetracaine	↓	Local anaesthetic
			Lidocaine	↓↓	Local anaesthetic; Ventricular arrhythmia
			Valproic acid	↓	Epilepsy; Bipolar Disorder; Migraine
			Brivaracetam	↓	Epilepsy
SCN2A	Adiposity		Zonisamide	↓↓	Epilepsy
			Tetracaine	↓	Local anaesthetic
			Valproic acid	↓	Epilepsy; Bipolar Disorder; Migraine
			Brivaracetam	↓	Epilepsy
VEGFA	Hematocrit, Hemoglobin, RBC.traits, Renal.Function, Urate	Carvedilol		↓↓↓↓	Hypertension; Angina; Heart Failure
YES1	Non.Pleiotropic		Dasatinib	↓↓	Chronic myeloid leukaemia

All pleiotropic associations of BP GWAS SNPs were extracted and categorised into groups of correlated traits. Some SNPs did not show any non-BP associations and were classified as non-pleiotropic. The genes linked to GWAS SNPs were determined by proximity to the SNP and cardiovascular plausibility. Only one gene per loci was included. Drug-gene interactions were obtained from Drug Bank and Comparative Toxicogenomics Database and drug indications were obtained from the British National Formulary and FDA labelled indications.

Legends to Figures.

Figure 1: Blood pressure regulation – blood pressure is the product of cardiac output and peripheral vascular resistance and these are regulated by a multitude of factors. This figure shows the spectrum of rare genomic mutations affecting blood pressure by perturbing specific physiological systems. Additionally, the role of polygenic variants are complex and integral to blood pressure regulation through pathways that are yet to be characterised. Blood pressure is a multifactorial trait and the circos background plot represents both the landscape of genetic variants and environmental and other factors that have a role in blood pressure regulation. The inner circle, represents the organ specific physiological pathways that affect blood pressure. The length of each segment is a relative representation of known genetic factors involved in that pathway. The outer circle represents the polygenic background and known environmental factors that influence multiple physiological pathways leading to the final blood pressure phenotype.

Figure 2: Genetic architecture of blood pressure and hypertension. The circos[102] plot shows depicts the monogenic and polygenic genetic variants identified by linkage, sequencing and genome wide association studies. Monogenic variants are large filled red circles and they are connected to their Clinical syndromes. The smaller blue, green and yellow filled circles are SNPs identified from genome wide association studies. The colour of the SNPs indicates whether the best association of the SNP was for systolic, diastolic or pulse pressure. FH – Familial hyperaldosteronism; AME – Apparent mineralocorticoid excess; PHA – Pseudohypoaldosteronim II; APA – Aldosterone producing adenoma; CAH – Congenital adrenal hyperplasia; HTNBRACH – Hypertension with brachydactyly; HSD3B2 - 3β-hydroxysteroid dehydrogenase deficiency; PGL1-5 – Paraganglioma; VHL – Von Hippel Lindau Syndrome; MEN – Multiple Endocrine Neoplasia II.

The top of the plot shows pleiotropic signals from PheWAS, which indicate lifestyle, environmental and early life influences on blood pressure linked to the location of the pleiotropic SNPs.

The histogram on the outer ring indicates the number of pleiotropic associations SNPs in that locus have. The taller the graph, the greater the number of pleiotropy.

Figure 3: Pleiotropic signals from phenome wide association studies. The Venn diagrams show the number of blood pressure SNPs that are significantly associated with other traits. The top panel is the global pleiotropic landscape of different phenotypic groups with the number of BP SNPs that overlap

with them shown within brackets. Here overarching phenotypic groups were condensed from a range of traits that fall under this category. More detailed representation of the constituents of the major phenotypic groups are represented in the bottom panel showing the contribution of individual traits and the degree of pleiotropy with blood pressure and the level of overlap between them.

Abstract

Streptococcus pneumoniae is a common nasopharyngeal colonizer, but can also cause life-threatening invasive diseases such as empyema, bacteremia and meningitis. Genetic variation of host and pathogen is known to play a role in invasive pneumococcal disease, though to what extent is unknown. In a genome-wide association study of human and pathogen we show that human variation explains almost half of variation in susceptibility to pneumococcal meningitis and one-third of variation in severity, and identified variants in *CCDC33* associated with susceptibility. Pneumococcal variation explained a large amount of invasive potential, but serotype explained only half of this variation. Newly developed methods identified pneumococcal genes involved in invasiveness including *pspC* and *zmpD*, and allowed a human-bacteria interaction analysis, finding associations between pneumococcal lineage and *STK32C*.

Streptococcus pneumoniae, or the pneumococcus, is a leading cause of pneumonia, meningitis, and bacteremia. Over 90 serotypes are known, which have varying prevalence of asymptomatic carriage and disease[1,2]. Some clonal genotypes have been associated with invasive disease, though as serotype is correlated with genetic background, finding how much each of these factors affects invasive propensity in clinical cases of disease is challenging.

Bacterial meningitis involves severe inflammation of the membranes surrounding the brain, the meninges, which is a response to the presence of bacteria in the cerebrospinal fluid (CSF)[3]. *S. pneumoniae* is the most common cause of bacterial meningitis and despite advances in vaccination and treatment case fatality rate is 17-20% and unfavourable outcome occurs in 38-50% of cases[4].

Knowledge of the contribution of genetic variability of humans and invading pathogens to pneumococcal meningitis susceptibility could guide development of new vaccines preventing the progression from asymptomatic carriage to invasive disease, whereas genetic variation associated with disease severity may guide new clinical intervention strategies during treatment[5]. However the effect of human genetics on pneumococcal meningitis is unknown – whether it affects the disease at all, and if so, which specific regions of the genome cause the effect. Historically, genetic association studies on bacterial meningitis have been held back by only assessing candidate genes, small sample sizes or poorly defined phenotypes[6]. More recent GWAS studies have found associations for children with meningococcal meningitis in Europe[7], and pneumococcal meningitis in Kenya[8].

In terms of pathogen variability, it is well known that the pneumococcal polysaccharide capsule, which determines its serotype, contributes to invasive propensity[1,2]. The pneumococcal genome also encodes a variety of proteins which directly interact with the host, mostly to enhance colonisation and avoid the host immune response[9]. Mouse models have shown that some antigens such *pspC* (*cbpA*) enhance virulence but are not essential in invasive isolates. Though the role of these antigens in colonisation and disease may be known, whether sequence variation at these loci has an effect on pathogenesis in human disease remains unclear. Previous small association studies have additionally suggested a role for platelet binding[10] and arginine synthesis[11] in pneumococcal meningitis, and analysis of within-host variation found that sequence variation of *dlt* and *pde1* are associated with pneumococcal meningitis[12,13].

Thus, because of a lack of large cohort studies combined with detailed clinical metadata, the overall role of pneumococcal variation in clinical cases of meningitis is as yet unknown. It has not been possible to calculate the degree to which different serotypes affect invasiveness compared to other factors (either genetic or environmental), or if there are serotype-independent loci which are involved in invasion. Bacterial genome wide association studies (GWAS) provide a way to identify pneumococcal sequence variation associated with meningitis, independent of genetic background in an unbiased manner. While GWAS is more challenging in bacteria than humans due to strong population structure and high levels of pan-genomic variation, recent methodological advances have helped overcome these issues[14–16].

We have collected data and samples from Dutch adults with meningitis between Jan 1, 2006, and July 1, 2014 in the prospective and nationwide MeninGene cohort[4]. Our study addresses previous limitations of genetic studies by collecting a large number of samples of both host and pathogen DNA from culture-proven cases of pneumococcal meningitis, along with detailed clinical metadata (supplementary table 1). We have performed genotyping and whole genome sequencing of this collection, a combined GWAS of host and pathogen in pneumococcal meningitis, the first time such a study has been attempted for a bacterial disease. We performed a GWAS separately in host and pathogen, continuing to develop new approaches to conduct the latter analysis. In both cases we have collected additional cohorts to replicate our findings (figure 1). We also had sequences available from both host and pathogen in 460 cases allowing analysis of interaction effects in a joint GWAS. Using these well characterised cohorts we explain the role of genetic variation of human and pathogen in pneumococcal meningitis.

Results

Human genetics influences pneumococcal meningitis susceptibility and severity

Before trying to find specific loci associated with meningitis, we first calculated the heritability of susceptibility and severity due to host genetics using the MeninGene cohort. While genetic associations have been found with invasive meningococcal disease[7] and susceptibility to infectious diseases more broadly[17,18], the heritability of adult meningitis and its outcome have not previously been calculated. We used two methods to calculate SNP heritability, which showed that variation in host genetics explains 29% ± 7% of the observed variation in pneumococcal meningitis susceptibility, and 49% ± 14% of the variation in meningitis severity (table 1).

Table 1: Human SNP heritability (h^2_{SNP}) of meningitis susceptibility and severity in Dutch adults. Heritabilities are shown on the liability scale (adjusted for population prevalence and case ascertainment ratio). We used two methods for each phenotype, GCTA and LDAK. The latter corrects for linkage disequilibrium when estimating the kinship between genotypes. All results showed significant evidence for a heritability above zero.

Phenotype	Method	Heritability	Error	P-value
Susceptibility (any species)	GCTA	0.22	0.03	2.4×10^{-6}
	LDAK	0.29	0.05	3.9×10^{-11}
Susceptibility (pneumococcal)	GCTA	0.25	0.05	2.4×10^{-6}
	LDAK	0.29	0.07	3.9×10^{-6}
Severity	GCTA	0.29	0.11	2.8×10^{-5}
	LDAK	0.49	0.14	1.4×10^{-4}

Finding that these traits were heritable we then used GWAS to search for specific loci associated with meningitis. Using the MeninGene cohort alone, one marker reached significance when testing for severity: position 64680775 (rs12081070) on chromosome 1, an intronic variant in *UBE2U* which was associated with unfavourable outcome (MAF = 0.43; OR = 1.63; $p = 2.0\times10^{-8}$) (supplementary figures 1-4). *UBE2U* is part of the ubiquitin pathway, but has not been previously associated with any disease or trait. Chromatin conformation capture data shows that the site of the most significantly associated variant interacts with *PGM1* and *ROR1* in a range of immune cell types including monocyte/macrophages, CD4/8 T cells, B cells and neutrophils (supplementary figure 5). *PGM1* encodes a phosphoglucomutase while *ROR1* is a protein of unknown function which has previously been associated with cancers[19] and pulmonary function[20]. There was evidence of association of rs12081070 with gene expression in a panel of tissues and cell

types but this was only significant in skin ($p = 5.7\times10^{-13}$)[21]. Six other loci showed suggestive significance (table 2), whereas in the Danish cohort, no variants reached genome wide significance (supplementary figures 6 & 7).

Table 2: Signals of human association in the MeninGene cohort. We report the lead SNP at each associated locus with MAF > 5% and $p < 1\times10^{-6}$, and nearby annotated genes. The suggestive signal in all meningitis cases was also present when restricted to pneumococcal cases, albeit with a lower p-value of 3.9×10^{-7}.

Position (SNP)	**Effect allele**	**MAF**	**OR**	**P-value**	**Annotation**
Susceptibility (any species)					
chr6:153582990 (rs3870369)	T	0.42	1.27	7.2×10^{-8}	Upstream of *RGS17*
Susceptibility (pneumococcal)					
chr6:117624549 (rs210967)	G	0.46	0.77	8.8×10^{-7}	*ROS1* intronic
chr18:48403560 (rs2850542)	T	0.43	0.65	7.6×10^{-8}	*ME2* promoter (2kb upstream of TSS)
chr22:47506160 (rs13057743)	G	0.33	0.74	5.5×10^{-7}	*TBC1D22A* intronic
Severity					
chr1:64680775 (rs12081070)	A	0.43	1.62	2.0×10^{-8}	*UBE2U* (5th intron)/*ROR1*
chr4:182823804 (rs2309554)	A	0.33	1.58	4.1×10^{-7}	*AC108142.1* intron
chr9:37382231 (rs72739603)	A	0.07	2.36	6.7×10^{-7}	*ZCCHC7/GRHPR*

Of the genes implicated in the single cohort, we noted that the *ME2* promoter variant rs2850542 is an eQTL for the same gene in whole blood ($p = 5.9\times10^{-20}$, supplementary figure 8A) and specifically in monocytes (FDR 5.1x10-26)[22]. There was also evidence of chromatin interaction of the variant location with *SMAD4* again in a range of immune cell types including monocytes, lymphocytes and neutrophils (supplementary figure 8B/C). This gene is involved in TGF-β signalling and invasion across the epithelium; the variant also showed evidence of an eQTL involving rs2850542 for *SMAD4* expression in tibial artery ($p = 8.6\times10^{-7}$)[23].

To improve our discovery power and mitigate false positives from batch effects, we then performed similar associations in the other cohorts. In an analysis of all available cases (MeninGene, Danish invasive disease, GenOSept, 23andme, UK biobank invasive disease) no hits were significantly associated with invasive disease (supplementary figure 9). However, the results for susceptibility to meningitis (MeninGene, Danish meningitis, UK

biobank ICD-10 code for meningitis) found that position 74601544 on chromosome 15 (rs116264669) was associated with the minor allele increasing susceptibility in all three studies ($p = 4.4 \times 10^{-8}$; MAF = 3%) (supplementary figures 10 & 11). This intronic SNP is located in *CDCC33*, a gene that has no prior association with infectious disease. *CDCC33* is expressed in whole blood and the brain[21] although there is no evidence of an eQTL involving this variant or SNPs in linkage disequilibrium with it. The disease-associated variant is located in a genomic region that interacts with the immunoglobulin superfamily containing leucine rich repeat 2 gene *ISLR2* on chromatin conformation capture analysis in macrophages (supplementary figure 12A) and CD8 T-cells (supplementary figure 12B); moreover a variant in complete linkage disequilibrium (rs80140040) with the meningitis susceptibility SNP shows evidence of eQTL with *ISLR2* in a number of tissues including brain ($p = 0.02$). *ISLR2* shows highest expression in the brain (neural tissues, supplementary figure 12C) and plays a role in the development of the nervous system[24] but remains poorly characterised notably in humans. Severity data had not been recorded in other cohorts, and there were too few cases that had resulted in death to allow using this as a proxy for unfavourable outcome in a meta-analysis.

The results from the heritability analysis and GWAS suggest that susceptibility to meningitis is caused by many SNPs with individually low effect sizes (a polygenic trait), and that this cohort size is underpowered to detect these. To determine whether we expected the addition of more samples to uncover new associations with a larger effect size, we used Bayesian mixture models to fit the distribution of effect sizes in the MeninGene cohort. The maximum posterior suggested that 89% of the SNP heritability was caused by 29 large effect size SNPs (oligogenic), with the remaining heritability explained by small effect size SNPs (supplementary table 3). This was further supported by a dynamic Bayesian model incorporating variance in small and large effects, which found support for a mixture of many small effects plus a small number of large effects (maximum posterior $\rho = 0.50$ - proportion of variance explained by sparse terms) (supplementary table 4).

The collection of these datasets gave us the opportunity to perform two further multi-cohort analyses related to sepsis and self-reported meningitis. In the first, we combined Danish bacteremia, GenOSept and self-reported cases of sepsis in the UK biobank, but found no significant hits. Furthermore, we found no evidence that sepsis from clinician diagnosed cases in the UK biobank (using ICD-10 codes) were heritable. Secondly, we meta-analysed 23andme's results for self-reported meningitis with self-reported cases in the UK biobank[17] – the reported hit in *CA10* did not replicate. Given the p-value in the original study was just significant, it is possible that this result was a false positive. This may also be an artefact of respondent's knowledge of whether they had bacterial meningitis, which requires expert knowledge to diagnose and distinguish from viral meningitis[25].

Multiple bacterial loci determine pneumococcal invasive potential

We first performed a heritability analysis to quantify the amount of variation due to the pneumococcal genome for each phenotype on the liability scale. We found that additive pneumococcal genetics explained much of variation in invasive propensity ($h^2 = 85\%$), but no evidence of heritability of meningitis severity ($h^2 = 0\%$). This suggests that invasive

bioRxiv preprint first posted online Aug. 7, 2018; doi: http://dx.doi.org/10.1101/386078. The copyright holder for this preprint

propensity is highly heritable, but that disease outcome is not determined by natural variation of pathogen genetics. The latter is not surprising as invasive disease is an evolutionary dead end for the pathogen so adaptations affecting virulence over the short course of infection are unlikely to be selected for. This is contrary to smaller studies which have suggested that bacterial genotype may help diagnose severe disease in a clinical setting[26], but consistent with a meta-analysis finding no effect of pneumococcal serotype on the risk-ratio of death from meningitis[27].

That pneumococcal invasiveness is affected by pneumococcal genetics is well known, but a quantitative estimate of by how much is unknown. The high heritability estimated here, suggests that in this population some bacteria are able to invade while others are not. This is consistent with some serotypes rarely found in invasive disease[2], and with wide genetic separation from invasive lineages. The current focus of pneumococcal vaccination, and the most well known invasiveness determinant, is serotype. We therefore calculated what proportion of variation in invasiveness can be attributed to the serotype. Although not adjusted directly for genetic background, logistic regression gave a variance in invasiveness explained by the observed serotypes using Nagelkerke's pseudo R^2 from logistic regression of 0.45, less than the total heritability.

Identification of pneumococcal invasiveness loci in multiple cohorts

Given that serotype does not explain all of the variation in invasive potential other pneumococcal factors associated with disease are likely to exist. We then looked at overall differences in the sequence variation between asymptomatic carriage and meningitis isolates. The amount of rare variation compared to common variation present in a population is informative of recent selection and population size changes[28]. An overall difference may therefore be informative of different selection on regions of the genome depending on the niche. In figure 2a we plot the site-frequency spectrum by niche and predicted consequence. Across the range of common minor allele frequencies (MAFs) in both niches the proportion of synonymous/nonsynonymous/intergenic/loss-of-function (LoF) mutations is as previously observed[29]; at low frequencies there is an excess of potentially damaging variants. Figure 2c shows the overall burden of damaging rare variants between carriage and invasive samples; in both LoF and damaging variants there was higher burden in carriage isolates (median LoF: invasive 7, carriage 11, W = 297440, $p < 1 \times 10^{-10}$; median damaging: invasive 22, carriage 26, W = 345370, $p = 8 \times 10^{-4}$),

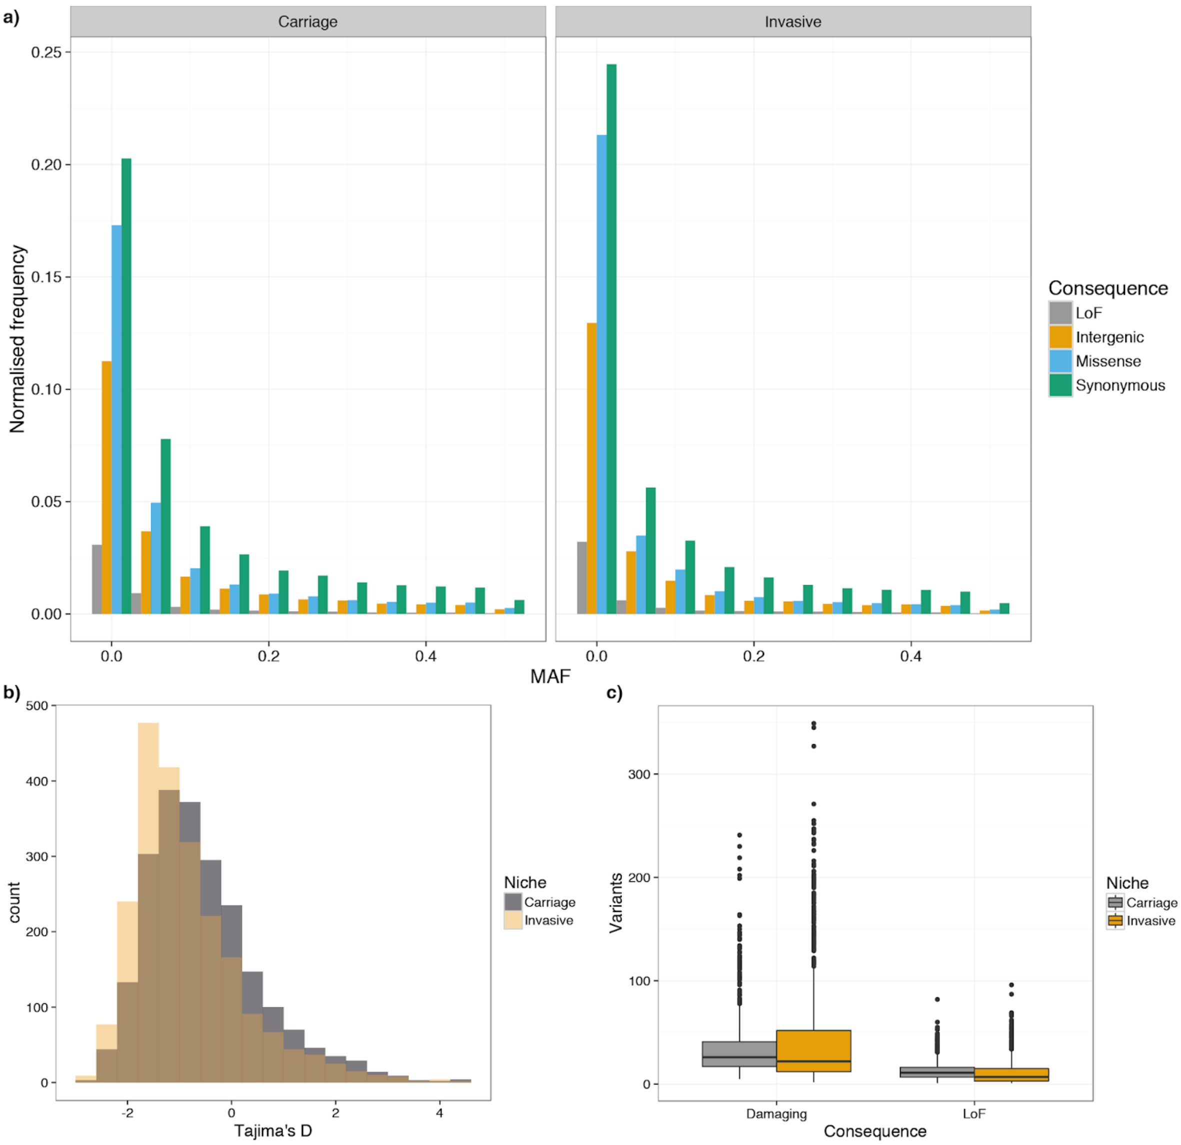

Figure 2: Differing burden and frequency of rare variation between invasive and carriage isolates, based on short variation called from mapping against the ATCC 700669 reference genome. Loss-of-function (LoF) are frameshift or nonsense mutations. a) The site frequency spectrum (SFS) stratified by niche and by predicted consequence. Frequency has been normalised with respect to the number of samples in each population. b) Histogram of Tajima's D for all coding sequences in the genome, stratified by niche. c) Boxplot of number of rare variants per sample, stratified by niche and predicted consequence. Damaging mutations are LoF mutations and missense mutations predicted damaging by PROVEAN.

In total, invasive samples had a higher proportion of rare variants than carriage samples. To quantify this difference and identify which regions of the genome are responsible for the excess of rare alleles we calculated Tajima's D, a statistic for neutral evolution, for each coding sequence in the genome, and looked for differing signs of selection between cases and controls. Deviations with $D < 0$ are indicative of selective sweeps and/or recent population expansion, whereas $D > 0$ is indicative of balancing selection and/or recent population contraction. In terms of differences between site-frequency spectrum (SFS), a negative D manifests as an excess of rare variants whereas a positive D manifests as a uniform distribution. We compared the distributions of D by gene in each phenotype (figure

2b). Genes in invasive isolates had a lower average D (difference in medians -0.34; W = 1996100, $p < 10^{-10}$) and a more positively skewed D (difference in skewness 0.30; 95% bootstrapped CI 0.17-0.44). This difference in D may be representative of a genuine difference in selection of variants in genes between niche, or may be due to a difference in recent population dynamics, for example due to the bottlenecks for invasion and transmission.

We then used GWAS to find locus effects on invasive disease, independent of serotype. As pneumococcal genomes vary extensively in their pan-genome[30], as well as having phenotypically important mosaic structural variants[31] and antigens alleles[32], we used a combination of methods to catalogue the population level variation then tested for associations while adjusting for population structure. We first performed this GWAS with disease severity, which was only measured in the Dutch cohort. Consistent with our estimates of no heritability, we found no loci of any type to be significantly associated with severity.

We then analysed meningitis versus carriage isolates. We first performed this analysis in the Dutch cohort (supplementary tables 5-7) revealing that many of our results involved rare variation, which has largely been ignored in previous bacterial GWAS studies[16]. This variation may be more important in a disease like meningitis where there is no pervasive selection for the phenotype. To improve the power and reliability of our results, we combined our Dutch cohort of meningitis and carriage samples with a cohort collected in South Africa, which included samples from carriage and cases of invasive pneumococcal disease. This gave a total of 5845 pneumococcal genomes to analyse. Table 3 shows the genes which were significant in this combined analysis using any of our association methods.

Table 3: Signals of bacterial association in the combined Dutch and South-African cohorts. Genes significant (Bonferroni corrected $P < 0.05$) in a pooled analysis of both cohorts with any of the association approaches, ordered by p-value. Odds-ratios are with respect to carriage samples. The genes in bold in the top half of the table are immunogenic, and are have previous evidence for association with virulence. For Tajima's D the effect size is the difference between D values, and for k-mers and LoF burden tests it is the odds-ratio. For some p-values the calculation only allows an upper bound to be produced. The locus tag in the ATCC 700669 reference is listed, along with the common gene name if available.

The genes noted in bold font in table 3 are all immunogenic[32], and have all previously been associated with pneumococcal virulence in animal models[33–36], but this is the first time an association has been shown in patients with invasive disease. Previous conclusions, drawn from protein binding to the Laminin receptor, have suggested that *pspC* (*cbpA*) is necessary for meningitis[37]. We predicted that both forms of *pspC* were absent in 13 meningitis isolates, though on closer inspection of the summary statistics from mapping and assembly these may also be an unresolved form of allele 8. Using our database of clinical data we also found that all of these patients had a severe ear, nose or throat infection, suggestive for direct spread of bacteria rather than crossing the blood-brain barrier. Three patients had clear bone destruction and/or pneumocephalus, which is proof for direct spread of the infection, and one patient had a skull defect. We further tested whether the two major forms of PspC were associated with meningitis specifically, as has previously been suggested[38], but did not find either to be overrepresented, when accounting for population structure. *dacB* is involved in preserving cell wall shape, and has shown to attenuate virulence in a mouse

model of lung infection. *zmpD* is homologous to IgA1 protease (*zmpA*)[39], and while it is immunogenic[32], its function is unknown – these results suggest a role in human cases of disease. The other genes in table 3 have not previously been directly associated with virulence or invasive disease in *S. pneumoniae*.

Interactions between host and pathogen genomes

It is possible that different host genotypes have varying susceptibility to different lineages, or strains carrying certain alleles. To test this we used the 460 samples where we had collected both human genotype and pneumococcal genome sequence (figure 1). In the first instance, to retain hypothesis-free approach of GWAS, we performed a host-pathogen interaction analysis between every pair of common bacterial variants and genotyped host variants. While we were able to perform the $2\text{x}10^{10}$ associations required, no pairs of loci surpassed the large multiple testing burden required by this analysis - a power calculation showed that we would have 80% power for finding an effect with MAF of 25% and OR of 4 (supplementary figure 13) in the absence of population structure. Through this approach, we can therefore rule out large single interaction effects (with OR > 4 and MAF > 25%) between host and pathogen in cases of meningitis.

Given the difficulty of reaching significance for this large number of tests, we then went on to consider regions with strong prior evidence for being involved in host-pathogen interaction. *S. pneumoniae* has many virulence factors, some of which are known to interact with specific human proteins[9]. We were interested in the interactions where the pneumococcal protein contains sequence variation, ideally somewhat independent of genetic background. These regions have a higher power to be detected in an association analysis, and the higher rate of variation is potentially a sign of diversifying selection, which may mean the variation is more likely to be associated with specific interactions with the human immune system. We tested for an association between host genotype and the allele of three antigens selected for their variability and immunogenicity: PspC (CbpA), PspA, and ZmpA. For all of the antigen alleles with enough observations (supplementary table 8) we performed an association against all imputed human variants as above, and using a more accurate imputation of the *CFH* region due to its potential relevance in these interactions.

None of the bacterial antigen alleles were significantly correlated with variants in their human interacting-protein counterparts at the suggestive level ($p < 10^{-5}$). However, there were two associations of a *cbpA* allele reaching genome-wide significance elsewhere in the genome. Supplementary figure 14 shows a locuszoom plot of each of these associations. The first is between *cbpA*-8 and position 148788006 on chromosome 6 (MAF = 0.08; OR = 9.20; p = $4.1\text{x}10^{-9}$). This is in *SASH1*, which has previously been found to have decreased expression during meningococcal meningitis (https://www.ebi.ac.uk/arrayexpress/experiments/E-GEOD-11755/) . The second is between pspC-9 and position 98891272 on chromosome 13 (MAF = 0.16; OR = 6.30; p = $3.6\text{x}10^{-8}$), in *FARP1*, a gene not previously associated with infectious disease. Of note, we could find no published evidence of chromatin confirmation capture interaction or eQTL effects with either of these human variants.

We attempted to reduce the multiple testing burden by reducing the dimension of the pathogen genotype, which takes advantage of the extensive genome-wide correlation between variants. To give a straightforward biological interpretation we used hierarchical Bayesian clustering to define lineages, and tested whether pathogen genotypes, so defined, were associated with host genotype. We ran associations with lineages with at least 10% of samples in the subphenotype (supplementary table 9). The only result reaching genome-wide significance was an association between cluster eight (serotypes 9N/15B/19A, which have no overall association with invasive disease over carriage) and variants on chromosome 10 (supplementary figure 15). The lead variant (rs10870273) is at position 134046136 on chromosome 10 (MAF = 0.27; OR = 4.28; $p = 1.2\times10^{-8}$) located in an intron of STK32C, a serine/threonine kinase highly expressed in the brain. The high effect size estimated for the interaction is consistent with the power predicted in supplementary figure 13.

Discussion

How genetics can affect susceptibility to and severity of pneumococcal meningitis has not been systematically investigated. We used multiple independent cohorts to perform human and pathogen GWAS to investigate the genetics of pneumococcal meningitis. We found no evidence for pathogen genetics affecting the severity of disease, whereas human genetics explained 49% ± 9% of this variation. In our Dutch cohort, variation near *UBE2U* and *ROR1* was significantly associated with severity. Our findings suggest that sequencing of the pathogen is likely to be uninformative for predicting disease progression, whereas further investigation of the host (and these genes in particular) may lead to greater insights into the mechanism behind severe cases of meningitis.

Host genetics explained 29% ± 7% of variation in susceptibility to meningitis, and a pooled GWAS analysis with our Danish cohort and the UK biobank found an association at *CDCC33*. This gene does not have a currently known function which is related to immunity, so this association may provide a new avenue with which to approach host studies; functional genomic data suggest a further possible mechanism for the susceptibility associated variant through interacting at a distance with and modulating expression of the brain expressed leucine-rich repeat and immunoglobulin (LIG) family protein gene *ISLR2*. By analysing the distribution of effect sizes, we found that meningitis susceptibility is likely to be affected by both a small number of large effect variants (oligogenic), and a large number of small effect variants (polygenic). We found no evidence of association between pneumococcal meningitis and *CFH*, which has previously been associated with meningococcal meningitis[7], nor at any other candidate locus. We were also not able to report a previous finding in *CA10* from self-reported meningitis status, pointing to a need for careful clinical phenotyping needed in studies of hard to diagnose diseases such as bacterial meningitis.

Research of the role of pneumococcal variation in invasive potential in large epidemiological studies has mostly been focused on serotype variation. The lack of cohorts with whole genomes and invasive phenotypes has not allowed determination of other virulence factors in human disease – it is only with large cohorts of whole genome sequences that contributions to pneumococcal phenotypes can be systematically attributed to serotype or other genetic variation. With our large collection of genomes we were able to determine that the bacterial genome is crucial in determining invasive potential, with serotype likely to be the main factor (45% of variance explained). We went on to perform a combined analysis using 5892 pneumococcal genomes from two independent cohorts to find specific variation associated with invasive disease. We found five genes independent of genetic background and serotype to be associated with invasive disease. This showed a role for the virulence genes *cbpA* (*pspC*), *dacB* and *psrP* in human disease for the first time, and a new association with the loss of expression of the immunogenic protein *zmpD*.

Our cohort also allowed a joint analysis of bacterial and human sequencing data. Though the high dimension of data required more samples to find interaction effects of modest effect

sizes, through biologically guided dimension reduction we were able to show evidence for possible enrichment of certain pathogen genotypes in certain host genotypes.

Pneumococcal meningitis, although a clinically important area of study due to its poor prognosis, is difficult to study. It is a relatively rare disease, challenging to diagnose in a timely manner, and requires a well set-up study to record the causal pathogen. Severe cases of meningitis are rare and may be difficult to record due to the need to follow up patients. Although there are no more current cohorts available to validate our results in, our findings suggest more cases should be collected to find further associations. Further replication using in vivo models will be necessary to confirm our results associating genes not previously known to be involved in pneumococcal meningitis.

Phenotype heterogeneity, here between causal organism, age of host infected and immunocompromised status may make replication of results with a large number of samples difficult. While we attempted to address this by looking for differences between sub-phenotypes, our sample size was likely too low to draw firm conclusions. It has been proposed that one reason why common variants associated with variation in infectious disease may be hard to find is that over human history they would have been selected against, and are therefore purged from the population[18,40]. Future genetic studies of meningitis should continue to collect samples with detailed clinical data, including the causal pathogen, to minimise phenotype heterogeneity.

Methods

Human genotyping and quality control

We performed genotyping using the Illumina Omni array, and called genotypes from normalised intensity data using optiCall[41]. For data taken from other platforms, we merged cases and controls only at sites in the intersection of the genotyping arrays used. We then performed basic quality control steps to first remove low quality samples, then low quality markers[42]. Samples with a heterozygosity rate three standard deviations away from the mean, or over 3% missing genotypes were removed. Markers with over 5% missing genotypes, significantly different ($p < 10^{-5}$) call rate between cases and controls, MAF < 1% or out of Hardy-Weinberg equilibrium ($p < 10^{-5}$) were removed. Using an LD-pruned set of markers, we estimated sample relatedness with KING[43], and removed any duplicate samples. Using the same set of markers, we used eigenstrat to perform a PCA to check sample ancestry (supplementary figure 16)[44]. Samples closer than third-degree relation and samples of non-European ancestry (which we defined as PC1 < 0.07) were removed for heritability analysis, initial association attempts and analysis with Subtest. We manually inspected intensity plots for any associated markers using Evoker[45], and removed any miscalled sites. Finally, we removed markers significantly associated with control batch ($p < 5 \times 10^{-8}$).

All markers were reported with respect to the reference allele and coordinates of GRCh37. We imputed markers using the HRC as a reference panel with the Sanger Imputation Server[46–48]. For the Danish samples, we instead used the Michigan imputation server due to the decreased number of markers available from merging two different genotyping arrays[49]. For greater accuracy, we reimputed the *CFH* region was imputed using impute2 with 1000 Genomes and GoNL as reference panels[50–52]. We removed resulting markers with MAF < 1%, HWE $p < 10^{-5}$ or INFO scores < 0.7 leaving 6.8M markers for association testing and heritability estimation.

Association of human variation

Throughout, we used a Glasgow Outcome Scale score[53] of anything less than five (any long term disability or death) to define unfavourable outcome. We performed the association study using bolt-lmm[54,55], using the LD-pruned set of genotyped markers to estimate the kinship matrix, and then calculating association statistics for all genotyped and imputed sites passing the above quality control thresholds. For the Dutch samples we included whether the patient was immunocompromised as a fixed effect (10% of cases), assuming that no control samples were immunocompromised (1% population prevalence[56,57]). To estimate heritability, we used two methods: GCTA-GREML[58] (as implemented in bolt-lmm) and LDAK v5[59]. For both, we only used samples passing the stricter thresholds for ancestry and relatedness. Estimates of heritability were transformed from the observed scale to the liability scale using a population prevalence of meningitis of 1×10^{-3}. When using Subtest to search for genetic difference between subphenotypes[60], we used default settings, using the weights

per marker calculated by LDAK to adjust for LD, and 1500 draws of 400 subsamples to generate null distributions of the test statistic.

We did not find evidence of overall differences between pneumococcal meningitis and other bacterial meningitis (pseudo-likelihood ratio (PLR) = 0.25; p = 0.75) or between severity and susceptibility (PLR = 0.14; p = 1.00). In the Danish cohort, there was no evidence of difference between meningitis and bacteremia (PLR = 311; p = 0.60). However this technique may rely on relatively highly associated SNPs, which were not found with this few samples. Susceptibility to any meningitis had a significantly higher heritability than its sub-phenotypes, which also have heritability above zero. This is more consistent with some difference in genetic architecture between the phenotypes.

To infer the distributions of effect sizes on meningitis, we ran bayesR[61] and the Bayesian Sparse Linear Mixed Model (BSLMM), as implemented in gemma[62]. For both models, we used the genotyped sites (~630k) in the Dutch data using all meningitis cases as the phenotype. For bayesR we used version 2 of the software, using the '-shuffle' option to increase computational efficiency. We ran the MCMC in each case with default settings: 5×10^5 iterations, discarding the first 2×10^5 as burn-in and sampling every tenth iteration. We ran BSLMM using a probit link function for 1×10^6 iterations, discarding the first 10^5 as burn-in and sampling every tenth iteration. In both cases we report the mean value of each hyperparameter in the posterior.

To perform associations using the UK biobank we used bolt-lmm, following the recommended protocol for analysing the available genetic data[55]. We extracted case samples with self-reported meningitis or sepsis/septicaemia (data-field 20002), with a diagnosis of meningitis (data-field 41202 having a value of G01, G001, G002, G003, G008, A170, A390 or A321 at least once), and with a diagnosis of sepsis (A403, A409, A408 or A40 at least once). We randomly selected 3000 control samples from the remaining samples which had passed the UK biobank genetic quality control, which allowed for quicker analysis with little impact on effective sample size. Using this sample, we removed genotyped markers with MAF < 0.001 or a missing rate > 0.1, and used this to estimate kinships in bolt-lmm. We used bolt-lmm to perform association analysis of every imputed SNP site, including participant age as a fixed effect.

We used METAL to perform meta-analysis between different sets of studies[63]. We used the effective sample size to weight the beta and SE from each set of summary statistics, also adjusting the beta values and standard errors produced by bolt-lmm (supplementary table 10). We only retained markers which had been successfully imputed in all studies, to avoid effects of varying sample size at each locus.

Chromatin conformation capture data was tested and presented using the Capture HiC Plotter[64] and eQTL data from the GTEx Consortium[21].

Catalogue of bacterial variation

From the whole genome sequence data of bacteria in the cohort we called SNPs and short INDELs with respect to the ATCC 700669 reference[65]. We mapped reads with bwa mem[66], marked optical duplicates with Picard, and called variants with GATK HaplotypeCaller[67]. For INDELs we used the recommended hard filters. For SNPs we used the recommended hard filters to create an initial call set. We then applied GATK VariantRecalibrator using the following call sites as true positive priors: the intersection of SNPs called by both GATK and bcftools (Q10; 90% confidence); filtered SNPs from a carriage cohort of Karen infants[68] (Q5; 68% confidence); filtered SNPs from a carriage cohort of children in Massachusetts[30] (Q5; 68% confidence). After quality score recalibration we used 99.9% recall as a cutoff for SNPs to maximise sensitivity, and annotated the predicted effect of all coding variation using the variant effect predictor[69]. We defined LoF variants as either stop gained or frameshift mutations. We used PROVEAN with a score cutoff of < -2.5 to predict whether non-synonymous SNPs affected protein function[70].

We produced a core gene alignment using roary[71], where we used reciprocal best BLAST[72] to choose a cut-off of 95% BLAST ID that maximised the balanced accuracy. To produce a presence/absence matrix of accessory elements, to be used as variants in association testing, we mapped the annotated genes in each isolate to a manually curated reference set[32,73]. As a first pass we used cd-hit[74], and then used blastp against the genes which were unclustered after the first pass.

We counted variable length k-mers with a minor allele count of at least ten using fsm-lite[14]. In the Dutch data there were 11.7M informative k-mers, with 2.6M unique patterns. Using the mapping to the ATCC 700669 reference, we used cn.mops[75] to call CNVs. We used windows of 1kb, and used windows with support for a CNV in at least two samples. The number of reads mapping to each *ivr* allele in each sample was determined by using read pair information, as previously[12,31].

While the k-mer approach should directly assay or tag most variation at the population level, the allelic variation of the pneumococcal antigens may not be well captured. For example, *pspC* can be difficult to assemble due to repeats and copy number variation[76], and k-mers from *pspA* and *zmpA* may not map to each allele specifically due to orthologous and paralogous genes[39,77]. As these antigens have been shown to interact with the host immune system, we developed a way to classify the allele present in each isolate combining assembly and mapping statistics. For each antigen in each sample we mapped reads to a reference panel using srst2[78], and aligned annotated genes from the assemblies using blastp. We used coverage, number of SNP mismatches, number of INDEL mismatches and number of truncated bases as summary statistics for each reference allele from srst2, and equivalently percent ID, number of mismatches, number of gaps, E-value and bitscore from blastp. For *pspC*, we used an existing classification scheme of 11 alleles from 48 sequences[76] (supplementary figure 17). For *zmpA* and *pspA* we built trees from previously characterised alleles[32] (supplementary figures 18 & 19). Finding that the ancestral branches in the phylogenies were poorly supported, while the topology of clades were well resolved,

bioRxiv preprint first posted online Aug. 7, 2018; doi: http://dx.doi.org/10.1101/386078. we took a cut through the deep branches of the phylogeny to define four allele groups for *pspA* and three for *zmpA*. We ensured the training data were separable into these groups using PCA (supplementary figure 20). We tested the performance of four out-of-the-box classifiers on 20 *pspC* alleles spread across the population that we manually typed from the assemblies (supplementary table 11). Finding that an SVM with a linear kernel worked best, we used this to classify the allele of all antigens in all isolates using the summary statistics described above (supplementary figure 21).

Using the South African samples we counted k-mers, SNPs and INDELs and COGs in the same way, and annotated LoF function variants. We found 52215 SNPs and INDELs, 6.3M informative k-mers, with 1.5M unique patterns.

Association of bacterial variation

Using the SNP and INDEL alignment we built a phylogenetic tree from this alignment using fasttree[79], and calculated the kinship between each pair of strains as the distance between their MRCA and the midpoint root. We calculated heritability on the liability scale[80] using this kinship matrix with FaST-LMM[81]. To estimate contributions for specific variant components such as serotype, we used lasso regression with leave-one-out cross validation to select significant predictors[16] and Nagelkerke's pseudo R^2 to find the variance explained in phenotype[82,83]. To test the effect of capsule charge on phenotype we used previously measured zeta potentials in place of serotype[84], using the serogroup average when a serotype specific charge was not known. Invasiveness was not well predicted from capsule charge alone ($R^2 = 0.08$)[84], partly because of the unknown capsule charge for many of the serotypes observed.

For association of common variation (MAF > 1%) we compared SEER[14], using the first ten multidimensional scaling components as fixed effects to control for population structure, with FaST-LMM[81], which uses eigenvectors from the kinship matrix calculated from the SNP and INDEL alignment as random effects to control for population structure. The Q-Q plots using fixed effects were highly inflated (supplementary figure 22), so we used the linear mixed model throughout. To correct for multiple testing we used the number of unique patterns as the number of tests in a Bonferroni correction, giving $p < 8.2\times10^{-7}$ for SNPs and $p < 1.9\times10^{-8}$ for k-mers. Inspection of the QQ-plots showed inflation of the test statistic for k-mers, so we used a higher threshold of $p < 10^{-16}$ instead. The same association methods was used with the antigen alleles and CNVs.

We considered whether the *ivr* locus, a phase variable inverting type I R-M system with six possible alleles [31], is associated with meningitis. Using mouse models, alleles at this locus have previously been shown to be selected for in carriage, whereas others are preferred in invasive disease[35,85]. The rapid variation of this locus allows simple associations independent of genetic background. To test for association of the *ivr* locus alleles with susceptibility and severity, we used a Bayesian hierarchical model we had previously developed to find differences in the proportion of alleles present in tissue types while accounting for heterogeneity within single colony picks[12]. We used the same priors (using allele prevalence calculated using long-range PCR from a subset of samples) and MCMC parameters as

bioRxiv preprint first posted online Aug. 7, 2018; doi: http://dx.doi.org/10.1101/386078. specified previously, but labelling with phenotype rather than tissue. We found no evidence that either allele frequencies or overall diversity had any association with invasive disease or carriage in clinical cases of meningitis (supplementary figures 23 & 24).

To calculate Tajima's D between phenotype groups we wrote a program in C++ using a function to calculate pairwise differences between strains we had previously optimised. Gaps or unknown sites were ignored. We calculated *D* for all coding sequences annotated in the ATCC 700669 reference, and p-values for difference between niche were calculated using 44000 null permutations of phenotype labels[86]. We applied a Bonferroni correction using the number of coding sequences tested.

Rare variants (MAF < 1%) could not be directly associated. Instead we applied a burden test[87], grouping variants by coding sequence. As burden tests lose power when variants have different directions of effect on the phenotype, we used only those variants predicted to cause a loss of function in one test, and those causing either loss of function (6825 variants) or predicted change in protein function in another (additional 26206 variants). These variants will have occurred on terminal (or close to terminal) branches and therefore population structure is less of an issue than for common variants. We used plink/seq to perform this association for each phenotype, applying a Bonferroni correction using the number of genes as the number of multiple tests.

Reasoning that power to detect individual variants may also be hampered by population structure as well as allele frequency, we also searched for a burden of missense variants of any frequency by gene. We used the LMM burden testing mode of pyseer[88] which allowed us to correct for population structure with the same model as above.

When performing analysis with both the Dutch and South African samples we pooled the genetic data, and performed the same association analysis as for the Dutch data alone. Where possible (associations using the linear mixed model) we included country as a covariate. The South African cohort also included host gender, age, collection year and HIV status and PCV-use at time of sampling. We included these as additional covariates for these samples. We were not able to use PROVEAN with this data, so only performed a burden test of damaging LoF variants. We used a significance threshold of $P < 0.05$ in the pooled analysis, after applying a Bonferroni correction for multiple testing based on the number of unique patterns as above. For all tests we ensured that the QQ-plots of the resulting p-values were not inflated (supplementary figure 25). We observed hits to simple transposons without cargo genes, which we therefore discarded as we assumed this was an artefact of their independence from population structure. We also found significant association of some BOX repeats[89], but as there are many copies we could not map these associations to a single region of the genome.

Interaction effects

We took 460 pneumococcal meningitis samples with matched pathogen and human sequence data which passed quality control thresholds for both data types. This has previously been applied to coding changes and host genotypes for HIV[90] and HCV[91], though

bioRxiv preprint first posted online Aug. 7, 2018; doi: http://dx.doi.org/10.1101/386078. these have much less variation than the pneumococcal population. To test all variants in a pairwise manner we converted the VCFs of human and pathogen calls into CSV files treating human genotypes as additive, and storing site and sample data separately for more efficient access by chunk[92]. The number of pairwise tests between all common variants was prohibitively large (10^{12}), so we only tested genotyped markers: 1.8×10^{10} pairs of variants passed filters of MAF > 5% and missing rate < 5% in both the human and pathogen data. We modified the association code of SEER [14] to extend the χ^2 test to a 3x2 table, and to perform a 3x2 Fisher's exact test (using https://github.com/chrchang/stats) when assumptions of the χ^2 test were violated. Those sites with $p < 5 \times 10^{-11}$ (a Bonferroni correction with alpha = 1, as an initial filter) were then tested using a logistic regression of the human SNP against the pathogen variant, with the first three components from multidimensional scaling of the pathogen kinship matrix included as covariates to adjust for pathogen population structure.

To test for an association between invading lineage and human genotype we re-ran hierBAPS on the 460 samples[93], which generated ten top level clusters (including a bin cluster) seven of which were large enough to test (supplementary table 9). We used bolt-lmm as above, but used whether the invading genotype was a member of the BAPS cluster as cases. We tested association of antigen alleles with frequencies over 10% in the sampled population in the same way (supplementary table 8).

Ethics statement

For the MeninGene study written informed consent was obtained from all patients or their legally authorized representatives. The studies were approved by the Medical Ethics Committee of the Academic Medical Center, Amsterdam, The Netherlands (approval number: NL43784.018.13). For bacterial carriage samples from the Netherlands, written informed consent was obtained from both parents of each child participant, and from all adult participants. Approvals for the 2009 and 2012/2013 studies in children and their parents (NL24116 and NL40288/NTR3614) and for the study in elderly adults (NTR3386) were received from a National Ethics Committee in the Netherlands (CCMO and METC Noord-Holland). For the 2010/2011 study a National Ethics Committee in the Netherlands (the STEG-METC, Almere) decided that approval was not necessary. The studies were conducted in accordance with the European Statements for Good Clinical Practice and the Declaration of Helsinki of the World Medical Association. The Danish Invasive Pneumococcal Disease Cohort was approved by Danish Data Protection Agency (record no. 2007-41-0229 and 01864 HVH-2012-046). Ethical permission was obtained from The Ethical Committee of The Capital Region of Denmark (H-B-2007-085 and H-1-2012-063). According to Danish Legislation, the Research Ethics Committee can grant an exemption from obtaining informed consent for research projects based on biological material under certain circumstances, and for this study such an exemption was granted.

IT IS WELL RECOGNIZED THAT DIFFERENT PATIENTS RESPOND IN DIFFERent ways to the same medication. These differences are often greater among members of a population than they are within the same person at different times (or between monozygotic twins).[1] The existence of large population differences with small intrapatient variability is consistent with inheritance as a determinant of drug response; it is estimated that genetics can account for 20 to 95 percent of variability in drug disposition and effects.[2] Although many nongenetic factors influence the effects of medications, including age, organ function, concomitant therapy, drug interactions, and the nature of the disease, there are now numerous examples of cases in which interindividual differences in drug response are due to sequence variants in genes encoding drug-metabolizing enzymes, drug transporters, or drug targets.[3-5] Unlike other factors influencing drug response, inherited determinants generally remain stable throughout a person's lifetime.

Clinical observations of inherited differences in drug effects were first documented in the 1950s,[6-9] giving rise to the field of pharmacogenetics, and later pharmacogenomics. Although the two terms are synonymous for all practical purposes, pharmacogenomics uses genome-wide approaches to elucidate the inherited basis of differences between persons in the response to drugs.

More than 1.4 million single-nucleotide polymorphisms were identified in the initial sequencing of the human genome,[10] with over 60,000 of them in the coding region of genes. Some of these single-nucleotide polymorphisms have already been associated with substantial changes in the metabolism or effects of medications, and some are now being used to predict clinical response.[3-5,11] Because most drug effects are determined by the interplay of several gene products that influence the pharmacokinetics and pharmacodynamics of medications, including inherited differences in drug targets (e.g., receptors) and drug disposition (e.g., metabolizing enzymes and transporters), polygenic determinants of drug effects (Fig. 1) have become increasingly important in pharmacogenomics. In this review, we focus on the therapeutic consequences of inherited differences in drug disposition and drug targets. An accompanying review[12] focuses on the pharmacogenetics of drug metabolism. This review is not meant to be exhaustive; rather, clinically relevant examples are used to illustrate how pharmacogenomics can provide molecular diagnostic methods that improve drug therapy.

GENETIC POLYMORPHISMS INFLUENCING DRUG DISPOSITION

The field of pharmacogenetics began with a focus on drug metabolism,[12] but it has been extended to encompass the full spectrum of drug disposition, including a growing list of transporters that influence drug absorption, distribution, and excretion.[3-5,13]

Figure 1. Polygenic Determinants of Drug Response.

The potential effects of two genetic polymorphisms are illustrated, one involving a drug-metabolizing enzyme (top) and the second involving a drug receptor (middle), depicting differences in drug clearance (or the area under the plasma concentration–time curve [AUC]) and receptor sensitivity in patients who are homozygous for the wild-type allele (WT/WT), are heterozygous for one wild-type and one variant (V) allele (WT/V), or have two variant alleles (V/V) for the two polymorphisms. At the bottom are shown the nine potential combinations of drug-metabolism and drug-receptor genotypes and the corresponding drug-response phenotypes calculated from data at the top, yielding therapeutic indexes (efficacy:toxicity ratios) ranging from 13 (65 percent:5 percent) to 0.125 (10 percent:80 percent).

DRUG METABOLISM

There are more than 30 families of drug-metabolizing enzymes in humans,[3,14] and essentially all have genetic variants, many of which translate into functional changes in the proteins encoded. These monogenic traits are discussed by Weinshilboum.[12] But there is an instructive example of a multigenic effect involving the CYP3A family of P-450 enzymes. About three quarters of whites and half of blacks have a genetic inability to express functional CYP3A5.[15] The lack of functional CYP3A5 may not be readily evident, because many medications metabolized by CYP3A5 are also metabolized by the universally expressed CYP3A4. For medications that are equally metabolized by both enzymes, the net rate of metabolism is the sum of that due to CYP3A4 and that due to CYP3A5; the existence of this dual pathway partially obscures the clinical effects of ge-

netic polymorphism of CYP3A5 but contributes to the large range of total CYP3A activity in humans (Fig. 2). The CYP3A pathway of drug elimination is further confounded by the presence of single-nucleotide polymorphisms in the *CYP3A4* gene that alter the activity of this enzyme for some substrates but not for others.[16] The genetic basis of CYP3A5 deficiency is predominantly a single-nucleotide polymorphism in intron 3 that creates a cryptic splice site causing 131 nucleotides of the intronic sequence to be inserted into the RNA, introducing a termination codon that prematurely truncates the CYP3A5 protein.[15] Although it is now possible to determine which patients express both functional enzymes (i.e., CYP3A4 and CYP3A5), the clinical importance of these variants for the many drugs metabolized by CYP3A remains unclear.

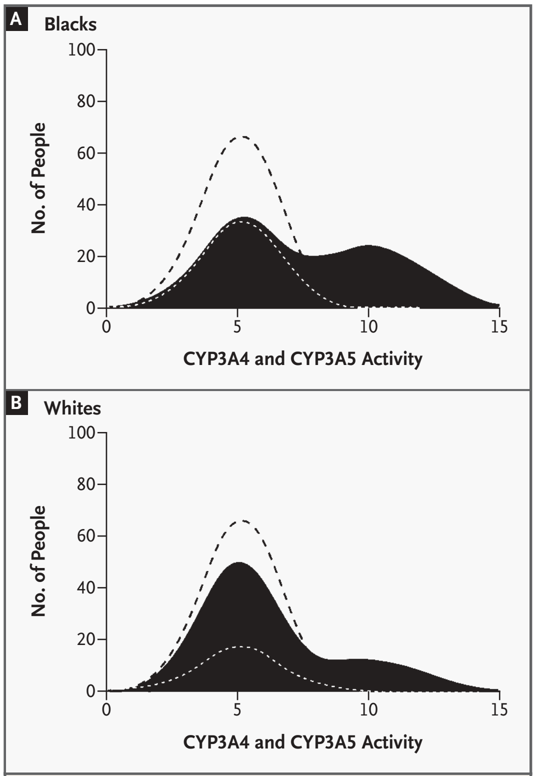

Figure 2. Simulated Activities of Cytochromes P-450 CYP3A4 and CYP3A5 in Blacks and Whites.

The simulated activities of CYP3A4 (black dashed lines) and CYP3A5 (white dashed lines) are shown in blacks (Panel A) and whites (Panel B), assuming a normal distribution and a 10-fold range in activity (shown in arbitrary units) among those expressing functional forms of these enzymes, and further assuming that all patients express CYP3A4, but that only 25 percent of whites and 50 percent of blacks express functional CYP3A5 because of genetic polymorphism. The solid area reflects the combined activity of CYP3A4 and CYP3A5 in the two populations for medications that are metabolized equally by the two enzymes.

DRUG TRANSPORTERS

Transport proteins have an important role in regulating the absorption, distribution, and excretion of many medications. Members of the adenosine triphosphate (ATP)–binding cassette family of membrane transporters[17] are among the most extensively studied transporters involved in drug disposition and effects. A member of the ATP-binding cassette family, P-glycoprotein, is encoded by the human *ABCB1* gene (also called *MDR1*). A principal function of P-glycoprotein is the energy-dependent cellular efflux of substrates, including bilirubin, several anticancer drugs, cardiac glycosides, immunosuppressive agents, glucocorticoids, human immunodeficiency virus (HIV) type 1 protease inhibitors, and many other medications (Fig. 3).[17,21,22] The expression of P-glycoprotein in many normal tissues suggests that it has a role in the excretion of xenobiotics and metabolites into urine, bile, and the intestinal lumen.[23,24] At the blood–brain barrier, P-glycoprotein in the choroid plexus limits the accumula-

Figure 3 (facing page). Functional Consequences of Genetic Polymorphisms in the Human P-Glycoprotein Transporter Gene *ABCB1* (or *MDR1*).

The schematic diagram of the human P-glycoprotein was adapted from Kim et al.,[18] with each circle representing an amino acid and each color a different exon encoding the corresponding amino acids. Two single-nucleotide polymorphisms in the human *ABCB1* gene have been associated with altered drug disposition (Panels A, B, C, and E) or altered drug effects (Panel D). The synonymous single-nucleotide polymorphism (a single-nucleotide polymorphism that does not alter the amino acid encoded) in exon 26 (the 3435C→T single-nucleotide polymorphism) has been associated with higher oral bioavailability of digoxin in patients homozygous for the T nucleotide (Panel A [C_{max} denotes maximal concentration])[19] but lower plasma concentrations after oral doses of fexofenadine (Panel B)[18] and nelfinavir (Panel C).[20] This single-nucleotide polymorphism has also been linked to better CD4 cell recovery in HIV-infected patients who are treated with nelfinavir and other antiretroviral agents (Panel D).[20] The single-nucleotide polymorphism at nucleotide 2677 (G→T) has been associated with lower plasma fexofenadine concentrations in patients homozygous for the T nucleotide at position 2677 (Panel E).[18] The panels have been adapted from Kim et al.,[18] Hoffmeyer et al.,[19] and Fellay et al.[20]

tion of many drugs in the brain, including digoxin, ivermectin, vinblastine, dexamethasone, cyclosporine, domperidone, and loperamide.[23-25] A synonymous single-nucleotide polymorphism (i.e., a single-nucleotide polymorphism that does not alter the amino acid encoded) in exon 26 (3435C→T) has been associated with variable expression of P-glycoprotein in the duodenum; in patients homozygous for the T allele, duodenal expression of P-glycoprotein was less than half that in patients with the CC genotype.[19] CD56+ natural killer cells from subjects homozygous for 3435C demonstrated significantly lower ex vivo retention of the P-glycoprotein substrate rhodamine (i.e., higher P-glycoprotein function).[26] Digoxin, another P-glycoprotein substrate, has significantly higher bioavailability in subjects with the 3435TT genotype.[19,27] As is typical for many pharmacogenetic traits, there is considerable racial variation in the frequency of the 3435C→T single-nucleotide polymorphism.[28-30]

The 3435C→T single-nucleotide polymorphism is in linkage disequilibrium with a nonsynonymous single-nucleotide polymorphism (i.e., one causing an amino acid change) in exon 21 (2677G→T, leading to Ala893Ser) that alters P-glycoprotein function.[18] Because these two single-nucleotide polymorphisms travel together, it is unclear whether the 3435C→T polymorphism is of functional importance or is simply linked with the causative polymorphism in exon 21. The 2677G→T single-nucleotide polymorphism has been associated with enhanced P-glycoprotein function in vitro and lower plasma fexofenadine concentrations in humans,[18] effects opposite to those reported with digoxin.[27]

The associations between treatment outcome and genetic variants in *CYP3A4*, *CYP3A5*, *CYP2D6*, *CYP2C19*, the chemokine receptor gene *CCR5*, and *ABCB1* have been examined in HIV-infected patients receiving combination antiretroviral therapy with either a protease inhibitor or a nonnucleoside reverse-transcriptase inhibitor.[20] The *ABCB1* 3435C→T polymorphism was associated with significant differences in the plasma pharmacokinetics of nelfinavir (Fig. 3) and efavirenz. Recovery of the CD4 cell count was significantly greater and more rapid in patients with the TT genotype than in patients with either the CT or the CC genotype (Fig. 3). Of many variables evaluated, only the *ABCB1* genotype and the base-line number of HIV RNA copies were significant predictors of CD4 recovery.[20] However, the *ABCB1* 2677G→T single-nucleotide polymorphism was not genotyped, so it remains unclear whether the 3435C→T polymorphism is causative or is simply linked with another polymorphism that is causative.

This example illustrates a common problem in association studies, namely, biologic plausibility. It is not obvious how greater efficacy (CD4 recovery) could be linked to a single-nucleotide polymorphism associated with lower plasma drug concentrations, unless there are specific effects of the *ABCB1* polymorphisms that cause decreased drug efflux from CD4 leukocytes. Overexpression of the gene for another ABC transporter (*ABCC4*, or *MRP4*) confers resistance to some nucleoside antiretroviral agents (e.g., zidovudine).[31] Despite the uncertainty about the mechanisms involved, the clinical value is that a host genetic marker can predict immune recovery after the initiation of antiretroviral treatment and, if validated, may offer a new strategy in tailoring HIV therapy.

GENETIC POLYMORPHISM OF DRUG TARGETS

Genetic variation in drug targets (e.g., receptors) can have a profound effect on drug efficacy, with over 25 examples already identified (Table 1).[3-5] Sequence variants with a direct effect on response occur in the gene for the β_2-adrenoreceptor, affecting the response to β_2-agonists[43,44]; arachidonate 5-lipoxygenase (ALOX5), affecting the response to ALOX5 inhibitors[42]; and angiotensin-converting enzyme (ACE), affecting the renoprotective actions of ACE inhibitors.[32] Genetic differences may also have indirect effects on drug response that are unrelated to drug metabolism or transport, such as methylation of the methylguanine methyltransferase (MGMT) gene promoter, which alters the response of gliomas to treatment with carmustine.[63] The mechanism of this effect is related to a decrease in the efficiency of repair of alkylated DNA in patients with methylated MGMT. It is critical to distinguish this target mechanism from genetic polymorphisms in drug-metabolizing enzymes that affect response by altering drug concentrations, such as the thiopurine methyltransferase polymorphism associated with the hematopoietic toxicity of mercaptopurine[64-66] and susceptibility to radiation-induced brain tumors.[67]

The β_2-adrenoreceptor (coded by the *ADRB2* gene) illustrates another link between genetic polymorphisms in drug targets and clinical responses. Genetic polymorphism of the β_2-adrenoreceptor can alter the process of signal transduction by these receptors.[43,44] Three single-nucleotide polymor-

Table 1. **Genetic Polymorphisms in Drug Target Genes That Can Influence Drug Response.***

Gene or Gene Product	Medication	Drug Effect Associated with Polymorphism
ACE	ACE inhibitors (e.g., enalapril) Fluvastatin	Renoprotective effects, blood-pressure reduction, reduction in left ventricular mass, endothelial function[32-40] Lipid changes (e.g., reductions in low-density lipoprotein cholesterol and apolipoprotein B); progression or regression of coronary atherosclerosis[41]
Arachidonate 5-lipoxygenase	Leukotriene inhibitors	Improvement in FEV_1[42]
β_2-Adrenergic receptor	β_2-Agonists (e.g., albuterol)	Bronchodilatation, susceptibility to agonist-induced desensitization, cardiovascular effects[43-50]
Bradykinin B2 receptor	ACE inhibitors	ACE-inhibitor–induced cough[51]
Dopamine receptors (D2, D3, D4)	Antipsychotics (e.g. haloperidol, clozapine)	Antipsychotic response (D2, D3, D4), antipsychotic-induced tardive dyskinesia (D3), antipsychotic-induced acute akathisia (D3)[52-56]
Estrogen receptor-α	Conjugated estrogens Hormone-replacement therapy	Increase in bone mineral density[57] Increase in high-density lipoprotein cholesterol[58]
Glycoprotein IIIa subunit of glycoprotein IIb/IIIa	Aspirin or glycoprotein IIb/IIIa inhibitors	Antiplatelet effect[59]
Serotonin (5-hydroxytryptamine) transporter	Antidepressants (e.g., clomipramine, fluoxetine, paroxetine)	5-Hydroxytryptamine neurotransmission, antidepressant response[60-62]

* The examples shown are illustrative and not representative of all published studies, which exceed the scope of this review. ACE denotes angiotensin-converting enzyme, and FEV_1 forced expiratory volume in one second.

phisms in *ADRB2* have been associated with altered expression, down-regulation, or coupling of the receptor in response to β_2-adrenoreceptor agonists.[43] Single-nucleotide polymorphisms resulting in an Arg-to-Gly amino acid change at codon 16 and a Gln-to-Glu change at codon 27 are relatively common, with allele frequencies of 0.4 to 0.6, and are under intensive investigation for their clinical relevance.

A recent study of agonist-mediated vasodilatation and desensitization[44] revealed that patients who were homozygous for Arg at *ADRB2* codon 16 had nearly complete desensitization after continuous infusion of isoproterenol, with venodilatation decreasing from 44 percent at base line to 8 percent after 90 minutes of infusion (Fig. 4). In contrast, patients homozygous for Gly at codon 16 had no significant change in venodilatation, regardless of their codon 27 status. Polymorphism at codon 27 was also of functional relevance; subjects homozygous for the Glu allele had higher maximal venodilatation in response to isoproterenol than those with the codon 27 Gln genotype, regardless of their codon 16 status (Fig. 4).[44]

These results are generally consistent with those of studies showing that the forced expiratory volume in one second (FEV_1) after a single oral dose of albuterol was higher by a factor of 6.5 in patients with the Arg/Arg genotype at codon 16 of *ADRB2* than in those with the Gly/Gly genotype (Fig. 4).[48] However, the influence of this genotype was different in patients receiving long-term, regularly scheduled therapy with inhaled β-agonists. Among these patients, those with the Arg/Arg genotype had a gradual decline in the morning peak expiratory flow measured before they had used medication, whereas no change was observed in patients with the Gly/Gly genotype.[47] In addition, the morning peak expiratory flow deteriorated dramatically after the cessation of therapy in patients with the Arg/Arg genotype, but not in those with the Gly/Gly genotype.[47] These data suggest that a codon 16 Arg/Arg genotype may identify patients at risk for deleterious or nonbeneficial effects of regularly scheduled therapy with inhaled β-agonists; the data also suggest that these patients may be candidates for alternative schedules of therapy, earlier initiation of antiinflammatory agents, or both. These findings are also consistent with the aforementioned desensitization of the β_2-adrenoreceptor in patients with a codon 16 Arg/Arg genotype.[44]

At least 13 distinct single-nucleotide polymorphisms have been identified in *ADRB2*.[46] This finding has led to evaluation of the importance of hap-

lotype structure as compared with individual single-nucleotide polymorphisms in determining receptor function and pharmacologic response. Among 77 white, black, Asian, and Hispanic subjects, only 12 distinct haplotypes of the 8192 possible *ADRB2* haplotypes were actually observed.[46] The bronchodilator response to inhaled β-agonist therapy in patients with asthma revealed a stronger association between bronchodilator response and haplotype than between bronchodilator response and any single-nucleotide polymorphism alone.[46] This is not surprising, because haplotype structure is often a better predictor of phenotypic consequences than are individual polymorphisms. This result suggests that it would be desirable to develop simple but robust molecular methods to determine the haplotype structure of patients.[68]

GENETIC POLYMORPHISMS WITH INDIRECT EFFECTS ON DRUG RESPONSE

Polymorphisms in genes encoding proteins that are neither direct targets of medications nor involved in their disposition have been shown to alter the response to treatment in certain situations (Table 2). For example, inherited differences in coagulation factors can predispose women taking oral contraceptives to deep-vein or cerebral-vein thrombosis,[80] whereas polymorphisms in the gene for the cholesterol ester transfer protein have been linked to the progression of atherosclerosis with pravastatin therapy.[75]

Genetic variation in cellular ion transporters can also have an indirect role in predisposing patients to toxic effects of drugs. For example, patients with variant alleles for sodium or potassium transporters may have substantial morbidity or mortality resulting from drug-induced long-QT syndrome. A mutation in *KCNE2*, the gene for an integral membrane subunit that assembles with HERG to form I_{Kr} potassium channels, was identified in a patient who had cardiac arrhythmia after receiving clarithromycin.[76] Additional *KCNE2* variants have been associated with the development of a very long QT interval after therapy with trimethoprim–sulfamethoxazole, with sulfamethoxazole inhibiting potassium channels encoded by the *KCNE2* (8T→A) variant.[77] Because *KCNE2* variants occur in about 1.6 percent of the population and their effect on drug actions can cause death, they are excellent candidates for polygenic strategies to prevent serious drug-induced toxic effects.

Genetic polymorphism in the apolipoprotein E (*APOE*) gene appears to have a role in predicting responses to therapy for Alzheimer's disease and to lipid-lowering drugs.[70,71,82,83] There are numerous allelic variants of the human *APOE* gene (e.g., *APOE* $\epsilon 3$, *APOE* $\epsilon 4$, *APOE* $\epsilon 5$, etc.), which contain one or more single-nucleotide polymorphisms that alter the amino acid sequence of the encoded protein (e.g., apolipoprotein $\epsilon 4$ has a Cys112Arg change). In a study of treatment of Alzheimer's disease with tacrine, 83 percent of the patients without any *APOE* $\epsilon 4$ allele showed improvement in total response and cognitive response after 30 weeks, as compared with 40 percent of patients with at least one *APOE* $\epsilon 4$ allele.[72] However, the greatest individual improvement in this study was seen in a patient with a single *APOE* $\epsilon 4$ allele, the unfavorable genotype, illustrating that a single gene will not always predict the response to a given treatment.[72] Follow-up studies indicate that the interaction between tacrine treatment and *APOE* genotype was strongest for women, again suggesting that many genes are involved in determining the efficacy of a treatment.[84]

The molecular basis for an association between apolipoprotein genotype and tacrine efficacy has not been elucidated, but it has been postulated that the *APOE* $\epsilon 4$ genotype may have an effect on cholinergic dysfunction in Alzheimer's disease that cannot be consistently overcome by therapy with acetylcholinesterase inhibitors such as tacrine. A randomized, placebo-controlled study of the noradrenergic vasopressinergic agonist S12024 in patients with Alzheimer's disease found the greatest protection of cognition in patients with the *APOE* $\epsilon 4$ genotype.[85] Confirmation of these results may offer an approach to the selection of initial therapy for Alzheimer's disease, with S12024 or similar medications being recommended for patients carrying an *APOE* $\epsilon 4$ allele.

Both phenotypic analysis and genotypic analysis of the *APOE* polymorphism have shown an asso-

Figure 4 (facing page). Functional Consequence of Genetic Polymorphisms in the β_2-Adrenoreceptor (Coded by the *ADRB2* Gene) at Codons 16 and 27.

A homozygous Glu genotype at codon 27 is associated with greater venodilatation after the administration of isoproterenol (Panel A).[44] A homozygous Arg genotype at codon 16 is associated with greater airway response to oral albuterol (Panel B)[48] and greater desensitization to isoproterenol (Panel C).[44] FEV_1 denotes forced expiratory volume in one second.

Table 2. Genetic Polymorphisms in Disease-Modifying or Treatment-Modifying Genes That Can Influence Drug Response.*

Gene or Gene Product	Disease or Response Association	Medication	Influence of Polymorphism on Drug Effect or Toxicity
Adducin	Hypertension	Diuretics	Myocardial infarction or strokes[69]
Apolipoprotein E (APOE)	Progression of atherosclerosis, ischemic cardiovascular events	Statins (e.g., simvastatin)	Enhanced survival[70,71]
Apolipoprotein E (APOE)	Alzheimer's disease	Tacrine	Clinical improvement[72]
HLA	Toxicity	Abacavir	Hypersensitivity reaction[73,74]
Cholesterol ester transfer protein (CETP)	Progression of atherosclerosis	Statins (e.g., pravastatin)	Slowing of progression of atherosclerosis by pravastatin[75]
Ion channels (HERG, KvLQT1, Mink, MiRP1)	Congenital long-QT syndrome	Erythromycin, terfenadine, cisapride, clarithromycin, quinidine	Increased risk of drug-induced torsade de pointes[76-78]
Methylguanine methyltransferase (MGMT)	Glioma	Carmustine	Response of glioma to carmustine[63]
Parkin	Parkinson's disease	Levodopa	Clinical improvement and levodopa-induced dyskinesias[79]
Prothrombin and factor V	Deep-vein thrombosis and cerebral-vein thrombosis	Oral contraceptives	Increased risk of deep-vein and cerebral-vein thrombosis with oral contraceptives[80]
Stromelysin-1	Atherosclerosis progression	Statins (e.g., pravastatin)	Reduction in cardiovascular events by pravastatin (death, myocardial infarction, stroke, angina, and others); reduction in risk of repeated angioplasty[81]

* The examples shown are illustrative and not representative of all published studies, which exceed the scope of this review.

ciation between *APOE* genotype and the response to lipid-lowering medications.[82,86-89] In most studies, patients with an *APOE ϵ2* allele had the greatest diminution of low-density lipoprotein cholesterol after drug therapy. The decrease was greatest for those with *APOE ϵ2*, followed by *APOE ϵ3* and then *APOE ϵ4*. This result was observed after treatment with a diverse range of lipid-lowering agents, including probucol, gemfibrozil, and many different 3-hydroxy-3-methylglutaryl-coenzyme A–reductase inhibitors (statins).[83] However, a significant effect of *APOE* genotype on the response to lipid-lowering agents has not been observed in all studies.[83]

In addition, although the *APOE4* allele was associated with less reduction in total and low-density lipoprotein cholesterol and a smaller increase in high-density lipoprotein cholesterol after fluvastatin therapy, there was no apparent influence of genotype on the progression of coronary artery disease or the incidence of clinical events.[88] Thus, prospective clinical evaluations with robust clinical end points and sufficient sample sizes are needed to define better the usefulness of the *APOE* genotype in selecting the treatment of hyperlipidemia and cardiovascular disease. The potential usefulness of the *APOE* genotype in predicting treatment response must be balanced by the concern that it could be used by insurance companies, health systems, and others to identify those at high risk for Alzheimer's disease, coronary artery disease, and possibly other illnesses.[82]

MOLECULAR DIAGNOSTIC METHODS FOR OPTIMIZING DRUG THERAPY

The potential is enormous for pharmacogenomics to yield a powerful set of molecular diagnostic methods that will become routine tools with which clinicians will select medications and drug doses for individual patients. A patient's genotype needs to be determined only once for any given gene, because except for rare somatic mutations, it does not change. Genotyping methods are improving so rapidly that it will soon be simple to test for thousands of single-nucleotide polymorphisms in one assay. It may be possible to collect a single blood sample from a patient, submit a small aliquot for analysis of a panel of genotypes (e.g., 20,000 single-nucleotide polymorphisms in 5000 genes), and test for those that are important determinants of drug disposition

and effects. In our opinion, genotyping results will be of greatest clinical value if they are reported and interpreted according to the patient's diagnosis and recommended treatment options.

CHALLENGES FOR THE FUTURE

There are a number of critical issues that must be considered as strategies are developed to elucidate the inherited determinants of drug effects. A formidable one is that the inherited component of the response to drugs is often polygenic (Fig. 1). Approaches for elucidating polygenic determinants of drug response include the use of anonymous single-nucleotide polymorphism maps to perform genome-wide searches for polymorphisms associated with drug effects, and candidate-gene strategies based on existing knowledge of a medication's mechanisms of action and pathways of metabolism and disposition. Both these strategies have potential value and limitations, as shown in previous reviews.[5,90,91] However, the candidate-gene strategy has the advantage of focusing resources on a manageable number of genes and polymorphisms that are likely to be important, and it has produced encouraging results in a number of studies.[20,52] The limitations of this approach are the incompleteness of knowledge of a medication's pharmacokinetics and mechanisms of action. Gene-expression profiling[92,93] and proteomic studies[94] are evolving strategies for identifying genes that may influence drug response.

One of the most important challenges in defining pharmacogenetic traits is the need for well-characterized patients who have been uniformly treated and systematically evaluated to make it possible to quantitate drug response objectively. To this end, the norm should be to obtain genomic DNA from all patients enrolled in clinical drug trials, along with appropriate consent to permit pharmacogenetic studies. Because of marked population heterogeneity, a specific genotype may be important in determining the effects of a medication for one population or disease but not for another; therefore, pharmacogenomic relations must be validated for each therapeutic indication and in different racial and ethnic groups. Remaining cognizant of these caveats will help ensure accurate elucidation of genetic determinants of drug response and facilitate the translation of pharmacogenomics into widespread clinical practice.

REVIEW

Genetics and genomics of Parkinson's disease

Michelle K Lin and Matthew J Farrer*

Abstract

Parkinson's disease (PD) is a progressively debilitating neurodegenerative syndrome. Although best described as a movement disorder, the condition has prominent autonomic, cognitive, psychiatric, sensory and sleep components. Striatal dopaminergic innervation and nigral neurons are progressively lost, with associated Lewy pathology readily apparent on autopsy. Nevertheless, knowledge of the molecular events leading to this pathophysiology is limited. Current therapies offer symptomatic benefit but they fail to slow progression and patients continue to deteriorate. Recent discoveries in sporadic, Mendelian and more complex forms of parkinsonism provide novel insight into disease etiology; 28 genes, including those encoding alpha-synuclein (*SNCA*), leucine-rich repeat kinase 2 (*LRRK2*) and microtubule-associated protein tau (*MAPT*), have been linked and/or associated with PD. A consensus regarding the affected biological pathways and molecular processes has also started to emerge. In early-onset and more a typical PD, deficits in mitophagy pathways and lysosomal function appear to be prominent. By contrast, in more typical late-onset PD, chronic, albeit subtle, dysfunction in synaptic transmission, early endosomal trafficking and receptor recycling, as well as chaperone-mediated autophagy, provide a unifying synthesis of the molecular pathways involved. Disease-modification (neuroprotection) is no longer such an elusive goal given the unparalleled opportunity for diagnosis, translational neuroscience and therapeutic development provided by genetic discovery.

Clinical features, main treatments and challenges

Parkinson's disease (PD) is a progressively debilitating neurodegenerative disease that becomes increasingly challenging to manage. Until recently, the underlying molecular cause(s) have remained elusive, as have hopes of disease-modification (neuroprotection). The need for advances in understanding and treating the disease is great as PD is the second most common neurodegenerative disorder after Alzheimer's disease. The estimated worldwide prevalence is 1% in the population >60 years of age, increasing to 4% at 80 years of age [1]. The median age of onset is about 70 years but about 4% of patients manifest early-onset disease (before they reach 50 years of age).

In PD, the clinical heterogeneity, disease course and response to medication vary widely [2]. Motor symptoms are associated with profound neuronal loss in the *substantia nigra pars compacta* (SN), depleting the striatum of dopaminergic inhibition. Hence, restorative dopaminergic therapies are the main treatment. Monoamine oxidase inhibitors are initially used to prevent endogenous dopamine catabolism; alternatively, L-DOPA, the metabolic precursor of dopamine, and/or dopamine agonists are used. In selected patients, deep brain stimulation (DBS) of striatal output pathways has also proven effective [3]. There are, however, several non-motor symptoms, of which many are non-dopaminergic and without remedy [4]. For example, 30% of patients develop mild-cognitive impairment within 5 years of motor symptoms and many develop dementia [5]. PD is clinically and/or pathologically distinct from other forms of parkinsonism (Box 1). A definitive diagnosis of PD requires the presence of Lewy bodies and Lewy neurites (proteinaceous intracellular inclusions) in the brain stem (midbrain), although these lesions are often more widespread [6,7]. Here, we review recent genetic and genomic findings in studies of PD, we provide some integration and synthesis of the molecular pathways involved, and we discuss the translational implications.

Early linkage and candidate gene studies

Classical linkage analysis has proven a powerful approach for the identification of specific disease-associated genes and mutations in families with multi-incident parkinsonism [8]. Genome-wide association and twin studies further demonstrate that even idiopathic sporadic

families with dominant, recessive or X-linked patterns of segregation. Not surprisingly, *in vivo* modeling in mammalian systems is challenging if the expectation is to recapitulate the human phenotype. Gene discovery efforts in PD have been expertly reviewed and we provide some historical context in Box 2. In this review, we focus on more typical, late-onset PD with Lewy body pathology, the disease type suffered by the majority of patients, and suggest how recent discoveries might unify existing ideas to suggest novel pathways and therapeutic targets.

In this context of genomic discovery, genes at three loci - alpha-synuclein (*SNCA*), leucine-rich repeat kinase 2 (*LRRK2*) and microtubule-associated protein tau (*MAPT*) - deserve special mention, although the molecular relationship between them has yet to be elucidated. Both *SNCA* and *LRRK2* assignments were originally implicated by the discovery (by linkage analysis) of pathogenic mutations that segregate within families, and these observations were extended into idiopathic PD by candidate gene studies. Combined pooled analysis by the Genetic Epidemiology of Parkinson's disease Consortium (www.geopd.org), literature meta-analysis (www.pdgene.org) and more recent genome-wide association studies (GWAS) have provided compelling support for the involvement of these loci.

Missense and multiplication mutations (duplication and triplication) in *SNCA* lead to PD, subsequent dementia and fulminant diffuse Lewy body disease on autopsy [11]. Levels of gene expression are inversely correlated with age at symptom onset. In rodents, *SNCA* overexpression may recapitulate many of the features of PD, whereas knockout mice are viable and fertile and appear to have little sign of disease [12]. The alpha-synuclein protein promotes presynaptic SNARE complex assembly, synaptic vesicle exocytosis and reciprocal plasmalemma endocytosis [13]. Alpha-synuclein protein aggregates, however, may also behave pathologically as prion proteins [14]. Transplants of fetal tissue into the striatum of human patients have been observed to develop Lewy-body pathology [15]. Similarly, iatrogenic inoculation of alpha-synuclein oligomers into mouse brain leads to widespread Lewy-like pathology, albeit requiring endogenous alpha-synuclein for transmission [16]. Hence, down-regulation or suppression of *SNCA* may represent one mechanism to slow disease progression [17]. Similarly, therapies that enhance the clearance of Lewy aggregates, including immunotherapies targeting potentially toxic forms of alpha-synuclein, might be neuroprotective [18].

LRRK2 parkinsonism is clinically indistinguishable from idiopathic PD. The age of onset and age-dependent cumulative incidence is similarly broad, although disease progression in carriers of *LRRK2* mutations is more homogeneous [19]. A founder haplotype has been noted for *LRRK2* p.G2019S in most populations. Penetrance appears to be ethnic-specific with a lifetime cumulative

Box 1. Parkinsonism and Parkinson's disease

Parkinsonism is used as an adjective to describe a movement disorder generally consisting of one of more features of tremor, bradykinesia and rigidity. The most common forms are drug-induced (for example, as a side-effect of antipsychotic neuroleptics), or vascular resulting from a stroke. When used as an adjective, the term parkinsonism does not imply that the symptoms are progressive or neurodegenerative, or that they are associated with a specific neuropathology. Parkinsonism may not respond to levodopa therapy. PD itself has the same core triad of symptoms, but it begins asymmetrically, one side of the body being more profoundly affected than the other, and postural instability is typically a feature. In PD, symptoms respond well to levodopa replacement therapy, and typically worsen with disease duration despite medication. Symptoms become bilateral in advanced PD, and dopaminergic imaging, using modalities such as DaTscan, highlights the same pattern of progression.

PD, but not parkinsonism, is often associated with a variety of autonomic problems (constipation, bowel and bladder incontinence, drooling), cognitive dysfunctions (from mild impairments in executive function to dementia), motor problems (from dystonia to dyskinesia), neuropsychiatric symptoms (mood disorders, such as depression to impulse control), sensory problems (from unexplained pain syndromes to hyposmia or anosmia) and sleep disorders (daytime sleepiness to REM sleep behavior disorder). Several of these problems, including dyskinesia, mood disorders and daytime sleepiness, may be associated with levodopa therapy or the use of dopamine agonists.

A definite diagnosis of PD is reserved for patients with Lewy body pathology and neuronal loss in the midbrain, which is often more widely distributed to involve the myenteric plexus, vagus and olfactory bulb. By contrast, parkinsonism may be associated with a variety of pathologies, including neurofibrillary tangles (such as in progressive supranuclear palsy, corticobasal ganglionic degeneration, or parkinsonism-dementia complex of Guam), to the predominant oligodendroglial alpha-synuclein pathology of multiple system atrophy, or predominant cortical Lewy pathology associated with dementia with Lewy bodies.

PD has a significant genetic component [9,10]. Mutant gene discovery by linkage with association provides an unequivocal burden of proof, and is the foundation required for translational neuroscience. Nevertheless, genetically defined carriers may have variable expressivity and penetrance and may never 'phenoconvert' to symptomatic disease. Age remains an important determinant, even in

Box 2. Genetic insights and evolving neuroscience

1997 A missense substitution, p.A53T, is discovered in the gene encoding alpha-synuclein (*SNCA*) in a family from Contursi, Italy whose members were susceptible to autosomal dominant, late-onset parkinsonism [56]. Alpha-synuclein, then known as 'Non-amyloid component of plaques' (NACP), provides a link between PD and Alzheimer's disease. Whether alpha-synuclein monomers, oligomers or fibrils are the toxic species becomes a topic for debate. Physiologically, the Zebra Finch homolog of *SNCA* is found to be required for song learning, pre-synaptic plasticity, and vesicle trafficking in neurotransmission.

Alpha-synuclein immunohistochemistry reveals much more occult Lewy pathology than had been visualized previously by hematoxylin and eosin (H&E) staining, and replaced the use of PGP9.5 (an antibody for Ubiquitin C-terminal hydrolase1 (UCHL1)) [136]. It is argued that familial and idiopathic forms of parkinsonism are the same disease, with similar ontology. Nevertheless, epidemiologists claim that the etiology of late-onset PD is environmental, rather than due to a genetic predisposition, supported by the results of twin studies. Further debate centers on whether ubiqinated Lewy body 'aggresomes' are pathologic or protective.

1998 Homozygous parkin deletions are linked to recessively inherited juvenile and early-onset parkinsonism, albeit without documented Lewy pathology [109]. Parkin mutations soon explain around 15% of all early-onset parkinsonism (in those younger than 45 years) [137]. As the parkin mutations affect a ubiquitin E3 ligase, the field focuses on proteasome inhibition, attempting to identify parkin's substrates and to nominate the toxic species. Patients with parkin mutations and Lewy or tau pathology have subsequently been described [138,139]. The crystal structure of the ubiquitin ligase reveals how its activity is regulated [116].

1999-2001 Candidate gene studies of polymorphic variability in *SNCA* and microtubule-associated protein tau (*MAPT*) highlight the roles of these genes in idiopathic, late-onset PD [57,140,141]. *MAPT* is implicated in progressive supranuclear palsy, in part because of the discovery of splicing mutations in another 4R-tauopathy, frontotemporal dementia with parkinsonism linked to chromosome 17 (FTDP-17) [44]. Large-scale GWAS provide further confirmation [9,52,55,142].

2003 *DJ-1* mutations that were discovered in early-onset parkinsonism [123] highlight a role for oxidative stress in PD. The findings help to justify the use of toxin-based models using 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) as an analog of the herbicide paraquat or the pesticide rotenone.

2003-2004 *SNCA* triplication and duplication mutations demonstrate a dose-dependent relationship between expression and pathogenicity [58,143-146] that is now supported by several mouse models. Lowering *SNCA* RNA and/or SNCA protein expression is nominated as a therapeutic target, supported by *in vivo* studies.

2004 Recessively inherited mutations are identified in the Pten-induced kinase 1 gene (*PINK1*) in early-onset parkinsonism [147]. By 2006, PINK1 was found to regulate Parkin recruitment and mitophagy [114,115]. *FBXO7* is within the same pathway, pointing to mitochondrial maintenance as a therapeutic opportunity [68]. Hexokinase is identified through interaction screens as an upstream component of the pathway [119]. PINK1 is shown to phosphorylate ubiquitin to activate parkin [117].

2004-2005 Dominantly inherited mutations are identified in the *LRRK2* gene in late-onset PD [32]. In 2005, *LRRK2* p.G2019S was linked to PD in Norwegian families [148], and found to be the major determinant of sporadic PD in Ashkenazi Jews and North-African Berbers. Kinase inhibition is nominated as a therapeutic strategy. Pleomorphic alpha-synuclein, 4R-tau or ubiquitin pathologies in affected carriers suggest that Lewy pathology should not be required for a definite diagnosis of PD [32]. LRRK2 is implicated in protein sorting or trafficking and in autophagy. Polymorphic variants in *LRRK2* are found to lower or increase the risk of sporadic PD [34].

2006 *ATP13A2* recessive mutations are identified in juvenile and early-onset parkinsonism [102]. Several lysosome-associated proteins have subsequently been linked to rare and rather atypical forms, including *ATP1A3* in rapid-onset parkinsonism-dystonia, and most recently *ATP6AP2* [71]. Polymorphic variants in the glucocerebrosidase gene *GBA1* are reproducibly associated with late-onset PD, highlighting a role for endosomal trafficking and lysosomal function [98].

2009 GWAS studies in PD confirm associations with *SNCA* and *MAPT*, and find evidence for additional loci [50-52].

2011 *VPS35* D620N is linked to dominant late-onset PD [63]. Many families have the same, albeit *de novo*, substitution that supports pathogenicity. By contrast, mutations in *EIF4G1* R1205H require further genetic and functional support for their assignment [149].

2013-2014 Mutations in *DNAJC13*, along with *VPS35*, in late-onset Lewy-body PD further highlight involvement of the retromer-WASH complex, endosomal protein sorting and trafficking [63,64,93].

2014 Further meta-analysis of GWAS supports known and novel loci. Nevertheless, for most loci the precise gene and underlying variability remain elusive.

risk of parkinsonism in p.G2019S carriers being 22% for Ashkenazi Jews (living in the US), 45% for Norwegians and 80% for Arab-Berbers [20-22], which is an important consideration for genetic counseling. For Ashkenazi Jews in Israel and Arab-Berbers in Tunisia the penetrance of disease is similar. In these countries, the frequency *of LRRK2* p.G2019S carriers in healthy controls is relatively high at 1 to 2% [23,24]. While genetic drift may be sufficient explanation for the high frequency of *LRRK2* p.G2019S carriers in healthy controls, positive selection may also contribute; *LRRK2* is associated with intestinal inflammatory disorders, immune response and kidney function, which if compromised may be most deleterious in hot climates [25-27]. Overall, only a small proportion (approximately 1%) of familial and sporadic PD is likely explained by *LRRK2* p.G2019S; other variability, such as the p.G2385R mutation, which is frequent throughout Asia, most significantly contributes to population-attributable risk [28] (Table 1).

At post-mortem, the majority of patients with pathogenic *LRRK2* mutations have Lewy-body disease [29]. However, even within families with the same mutation, pleomorphic pathologies have been observed. These include neurofibrillary tangles and tufted astrocytes (4R-tauopathies, as inclusion of *MAPT* exon 10 leads to the production of tau protein with four microtubule-binding domains), Tar DNA-binding protein 43 and ubiquitin immune-positive aggregates, or simply nigral neuronal loss with gliosis [30-32]. The variable penetrance and alternative end-stage pathologies most likely reflect genetic and/or environmental modifiers and stochastic factors, and have yet to be defined. Nevertheless, genetically defined cohorts of patients with parkinsonism such as LRRK2 p.G2019S parkinsonism might allow the identification of biomarkers of disease progression and inform clinical trials [19].

As the most common genetic cause of PD, LRRK2 and its protein interactions are a logical place to search for novel therapeutic targets. The domains of LRRK2 include armadillo and ankyrin repeat regions, leucine-rich repeat (LRR), Ras of complex GTPase (Roc), C-terminal of Ras (COR), kinase and WD40. LRRK2 is a ROCO protein, with a Ras GTPase and a kinase in one molecule; these activities have established roles in other organisms or cell types in dynamically modifying the actin cytoskeleton [33]. Pathogenic *LRRK2* mutations are primarily found in the GTPase Roc domain (p.R1437H, p.R1441C/G/H), the kinase domain (p.G2019S, p.I2020T) and intervening C-terminal of Roc (p.Y1699C), whereas susceptibility variants may also be found in protein-protein interaction domains (WD40 p.G2385R) [34]. Competitive inhibition of LRRK2 kinase is presently considered as one therapeutic target given that the p.G2019S mutation activates kinase activity, autophosphorylation and/or phosphorylation of substrates [35]. However, data on the first identified substrate, moesin, which is a filamentous actin tether, have not been recapitulated *ex* or *in vivo* [36]. LRRK2 protein levels also diminish with aging, with knock-in of *LRRK2* pathogenic mutations into the mouse genome [26] and with kinase inhibition [37,38]. LRRK2 probably functions as a dimer or higher molecular weight scaffold, with many protein-protein interactions. The activities of the Roc, COR and kinase domains are interconnected [39], and the many physiologic functions of the protein complex have yet to be fully elucidated.

Chr, chromosomal band; CI, confidence interval. [a]Genes within 100 kb of the most significantly associated SNP annotated from the UCSC genome browser (hg19). Odds ratios and *P*-values are the most significant findings from the PDGene database [150].

An association between PD and *MAPT* and the surrounding 17q21 locus results from an ancient paracentric inversion and was robustly implicated in clinical PD and in autopsy-confirmed series of PD in Caucasian populations [40-42]. Of note, similar variability in the *MAPT* locus has been unequivocally implicated in progressive supranuclear palsy, but not in Alzheimer's disease, although tau is a major component of the neurofibrillary tangle pathology in both conditions [43]. Splice and missense mutations were first described in frontotemporal dementia [44] and the inversion region was subsequently implicated in 17q21.31 microdeletion syndromes [45], but neither pathologic mutations nor tau pathology are found in PD. Thus, genetic variability in neighboring genes, within or flanking the *MAPT* inversion, may contribute. Some examples of additional genes and pathogenic mutations discovered through family-based linkage analysis of parkinsonism are summarized in Table 2.

Genome-wide association studies

While there are several genetic models for disease susceptibility, the 'rare variant common disease' model largely explains Mendelian heritability (one allele of major effect segregating with familial disease) whereas the 'common variant common disease' model (or multiple rare variants on common ancestral haplotypes) forms the theoretical basis of GWAS [46]. Built upon large, multi-institutional consortia, GWAS have dominated the search for novel genes in human traits in recent years. Collectively, more than 2,600 genomic regions (loci) of modest effect size (odds ratio <1.5) have been associated with >350 complex traits and have implicated underlying genes that play a role in disease causality or susceptibility [47]. Genome-wide genotyping, with approximately 0.5 to 1 million markers, is used to assess frequency differences in case-control designs, and is able to capture common genetic contributions to disease in linkage disequilibrium.

The first GWAS for PD were small and underpowered, showing little overlap in results [48,49]. Subsequently, there was an appreciation that larger numbers of markers and subjects are required for meaningful discovery and replication. Past North American and European efforts included analysis of familial parkinsonism [50] and of unrelated case-control series [51-54]. A web-based 'direct- to-consumer' effort, which is based on self report rather than clinical exam, is by far the largest study to date [9]. However, genomic imputation of single nucleotide polymorphisms (SNPs) in linkage disequilibrium allows datasets to be combined. In 2011, the International Parkinson Disease Genomics Consortium conducted a meta-analysis from five GWAS datasets [55]. Over 7 million SNPs based on approximately 1 million genotypes per individual were imputed *in silico*: the data were collected from 5,333 cases and 12,019 controls in the discovery phase, followed by 7,053 cases and 9,007 controls in the replication phase. Six loci previously associated with idiopathic PD were replicated and five new loci were identified (Table 1). Data from the latest mega-meta-GWAS, including over 13,000 patients with PD and 80,000 control subjects, are eagerly awaited.

Table 2 Mendelian mutations in familial parkinsonism

Gene	Mutation(s)	OMIM	Reference(s)
Dominantly inherited, late onset parkinsonism with Lewy pathology			
SNCA	Locus multiplication and missense mutations: A30P, E46K, H50Q, G51N, A53T	*168601*, *605543*	[56,58]
LRRK2	R1437H, R1441H, R1441G, R1441C, Y1699C, G2019S, I2020T	*607060*	[20,31,32]
VPS35	D620N	*614203*	[63,64]
EIF4G1	R1205H	*614251*	[149]
DNAJC13	N855S	*614334*	[93]
Recessively inherited, early-onset or X-linked atypical parkinsonism			
PARK2 (Parkin)	Numerous exon deletions, duplications and missense mutations	*600116*	[109]
PINK1	Rare locus and exon deletions. Numerous missense mutations, including E129X, Q129fsX157, P196L, G309N W437X, G440E, Q456X	*605909*	[147,151]
DJ-1	Deletions and missense: dup168-185, A39S, E64D, D149A, Q163L, L166P, M261I.	*606324*	[123]
DNAJC6	Splice site c.801 -2 A > G and truncating mutation Q734X	*615528*	[70]
ATP13A2	Missense: L552fsX788, M810R, G877R, G1019fsX1021. Small insertions and deletions: 1103insGA, del2742TT	*606693*	[102]
FBXO7	T22M, R378G, R498X	*260300*	[68]
PLA2G6	D331Y, R635Q,R741Q, R747W	*612953*	[152]
ATP6AP2	Splice site mutations		[71]
SYNJ1	Homozygous missense: R258Q	*615530*	[72]

OMIM, Online Mendelian Inheritance in Man, a database that catalogs all the known diseases with a genetic component.

Nevertheless, in the same Caucasian populations, the genetic variance explained is unlikely to increase in proportion to the sample size and investment. While additional loci may be nominated, these assignments are likely to be of smaller effect and will require independent validation.

Overall, the most significant GWAS associations are at chromosomal bands 4q22 and 17q21 and support *SNCA* and *MAPT* assignments, which were first identified in linkage and candidate gene studies [41,56-58]. Nevertheless, GWAS illustrates that the etiology of PD is genetically heterogeneous and novel loci may yet be identified, especially within under-represented non-Caucasian populations; for example, *PARK16*, *BST1* and *SYT11* were identified in a Japanese study [52]. Although a risk allele identified in one population should be a risk allele for all (the genotypic-attributable risk), their frequencies may be ethnically specific and lead to widely divergent population-attributable risks. For example, Caucasians have two major haplotypes (H1 and H2) for the *MAPT* locus; only H1 is present in Asian populations whereas the frequency of H2 is about 20% in Caucasians. The *MAPT* locus is significantly associated with PD in Caucasian studies but does not appear in a Japanese GWAS [51,52]. Conversely, the *PM20D1* locus was most clearly associated with PD in Japanese GWAS (5 to 8% differences between cases and controls) [52], whereas *PM20D1* allele frequencies in Caucasian studies were similar in cases and controls (1% difference) [51].

It is important to note that genomic loci are not disease genes *per se*. Within each genomic locus, there may be numerous genes of which one or all may be candidates contributing to disease risk. An illustration is the *GAK-DGKQ* locus that is significantly associated with PD [9,50,55]. *GAK* and *DGKQ* are in complete linkage disequilibrium and both proteins have important roles in clathrin-mediated vesicular trafficking [59,60]. Furthermore, no coding mutations have been identified in any GWAS locus or gene except for those previously identified through linkage studies in families (that is, *LRRK2* and *SNCA*). Rather, these associations are ascribed to subtle differences in wild-type gene expression, for which RNA silencing and overexpression models may be informative. Common variants of modest effect, on common haplotypes, may lead to modest transcriptional or functional changes. Directly genotyping a 'causal variant' will provide the greatest odds ratio for disease association and provides the rationale for locus-specific sequencing and further association testing. For some disease-associated loci, multiple rare variants of major effect may be responsible, in aggregate, although they will have occurred on the most frequent haplotypes.

Next-generation sequencing for PD

Most of the genetic variants in the human genome are a consequence of mutation with recent population expansion and are present at very low frequencies (<0.5%) [61]. Collectively, rare variants are more common than frequent variants in any given population and each individual has many unique *de novo* point mutations. If these cluster within specific genomic loci in patients with a disease such as PD, they highlight genes or mutational hotspots likely to confer disease susceptibility. To Sanger sequence gene-by-gene in search of a causative variant for PD is a time-consuming and cost-limited effort. Nevertheless, the detection of rare and unique variants via direct sequencing has become more affordable with the advancement of next-generation methods.

Within families, whole-exome sequencing (WES) has proven to be effective in uncovering rare causal mutations of major effect in small sample sizes, and is considerably less expensive than whole-genome sequencing. The first proof-of-concept work discovered pathogenic variants in Freeman-Sheldon syndrome in just four unrelated affected individuals [62]. The first WES study of parkinsonism revealed the p.D620N mutation in *VPS35* (the vacuolar sorting protein 35 gene) by sequencing affected cousin-pairs in autosomal dominant kindreds with late-onset disease [63,64]. These findings have been confirmed worldwide, suggesting that *VPS35* contributes to approximately 1% of familial parkinsonism and 0.2% of sporadic PD [65-67]. WES has become the fastest method for the identification of novel genes in parkinsonism, contributing to the discoveries of *FBXO7*, *WRD45*, *DNAJC6*, *DNAJC13*, *ATP6AP2* and *SYNJ1* in recent years [68-72].

Variants in non-coding and highly conserved genomic regions may also contribute to risk, and might explain the 'missing heritability' underlying complex trait disorders. Whole-genome sequencing (WGS) now enables the sequencing of untranslated regions (UTRs), including gene promoters, enhancers, introns, and 5′ and 3′ UTRs. These contribute to the regulation of gene expression directly through transcription-factor binding, via microRNA and noncoding RNA mechanisms and through alternative exon splicing, and can influence the phenotypic variance of some traits. Two examples relevant to parkinsonism include 5′ UTR expansions in *FMR1* in Fragile X-associated tremor-ataxia syndrome [73] and non-coding mutations in *ATP6AP2* that contribute to aberrant alternative splicing [71].

Next-generation DNA-sequencing panels can be used for novel mutation discovery in a locus-centric approach. In genome-wide family-based studies, when seeking to identify novel genes, it is prudent to examine and exclude those genes already implicated in parkinsonism (including developmental and aging syndromes as described earlier). Unique probes or amplicons can cover exonic regions or span entire loci, and target DNA can be barcoded and sequenced in parallel for multiple individuals. Such panels have many benefits: first, they provide affordable and rapid genetic diagnoses to better inform patient treatment, without problems arising from incidental findings [74]; second, they allow the discovery of as-yet-unknown mutations in genes known to be related to PD; and third, in aggregate, the results nominate genetic variants that may further explain the heterogeneity of clinical and pathologic presentations. Similar bioinformatic filters might be applied to WES or WGS *in silico*. In a gene-centric approach, with a limited number of genes studied per assay relative to WES or WGS, the interpretation is simplified. Nevertheless, custom capture or amplification methods can produce artifacts as oligomers may not be perfectly complementary to the human genome being interrogated, and this may introduce some allelic bias.

Another pitfall of next-generation sequencing (NGS) methods is the inability to sequence repetitive regions and structural variations. For example, *SNCA* multiplications, the *GBA* loci versus its pseudogene, or indeed any repetitive regions may confound sequence analysis; most sequence read lengths are relatively short (approximately 100 to 200 bp) and may be misaligned as a consequence. Almost half of the human genome consists of repeats that play an active role in genome evolution, although large structural rearrangements may result in disease [75]. Inadequate sequence read-depth may also lead to annotation errors. Most publically shared WGS has been performed at relatively low read depths; for example, the 1000 Genomes effort achieved 2x to 6x coverage (www.1000genomes.org). For WES, >100x coverage is considered necessary for diagnostic testing [76]. Nevertheless, specific NGS results should be validated by Sanger sequencing to prevent false positives. Higher-coverage sequencing, longer read lengths and innovative bioinformatic approaches continue to offer significant improvements.

In studies involving WES or WGS of familial PD, rare variants can be prioritized for validation and replication in additional samples by looking at the intersection of those shared by affected family members and not shared by elderly unaffected relatives. Typically, in approximately 58 Mb of exome sequencing approximately 80,000 single nucleotide variants are observed per individual, of which approximately 250 encode substitutions not annotated in public databases. To further reduce this number, a powerful approach has been to compare affected cousin-pairs, in contrast to affected sibling-pairs, to reduce the number of alleles shared by descent (from approximately 125 to approximately 31 variants). In 'pair-wise sharing analysis' non-synonymous missense mutations that have a frequency less than the incidence of PD (<0.003), which are evolutionarily conserved and predicted as damaging, are prioritized as good candidates for follow-up. However, caution is warranted in comparative analyses: the phenocopy rate of late-onset PD is approximately 18% in families in which a monogenic cause of disease is already defined [77]. The strategy may also exclude causal or risk variants. For example, *SNCA* p.A53T was the first mutation identified in PD but is neither evolutionarily conserved nor predicted to be deleterious [56].

Molecular pathways in PD

Many genetic components now appear to contribute to the pathogenesis of parkinsonism. It is largely unknown whether the proteins involved function in overlapping biological pathways, whose dysfunction results in the progressive loss of striatal dopaminergic innervation and death of midbrain nigral neurons. Nevertheless, some relationships, involving the perturbation of relatively few cellular systems, are apparent (Figure 1). The affected systems include synaptic transmission, endosomal trafficking, lysosomal-autophagy and energy metabolism or mitophagy.

Synaptic transmission

Alpha-synuclein protein is found abundantly at the presynaptic terminals of neurons and is involved in synaptic release [13] (Figure 1). Monomeric forms of alpha-synuclein may contribute to endophilin-A1-related membrane curvature, facilitating both synaptic vesicle exo- and endocytosis [78]. A tetrameric conformation has been proposed for alpha-synuclein and this might provide a parsimonious explanation of how amino-terminal point mutations lead to the same functional deficits [79,80]. The conformation of alpha-synuclein has previously revealed physiologic interactions with mitochondria [81] and with presynaptic tubulovesicular or endosomal structures when alpha-synuclein is overexpressed in transgenic mice [82].

At the synapse, LRRK2 levels regulate glutamate transmission, dopamine-dependent plasticity and striatal signal transduction [83,84]. LRRK2 protein levels and mutant-specific phenotypes have long been observed in neuritic outgrowth (affecting branching and length) in primary cultures [85,86] and in neurogenesis *in vivo* [87]. In *Drosophila*, LRRK2 kinase has been shown to regulate the EndoA phosphorylation cycle, and pathogenic mutations appear to impede synaptic endocytosis [88] (Figure 1). LRRK2 protein is also reported to interact with the dynamin superfamily of GTPases, which mediate both membrane scission in clathrin-induced endocytosis and mitochondrial fission and fusion [89]. In *Caenorhabditis elegans*, knockout of LRK-1 (the single homolog of mammalian *LRRK1* and *LRRK2*) leads to impairment in presynaptic protein sorting and axonal trafficking [90]. Several important functions have also been ascribed to the LRRK2 protein complex in non-neuronal cells, including kidney cells [26,91], and in innate immunity [92].

Figure 1 (See legend on next page.)

(See figure on previous page.)
Figure 1 Cellular processes implicated in familial late-onset, Lewy body parkinsonism. In late onset parkinsonism, which is most reminiscent of Lewy body PD, a novel synthesis is emerging whereby regulatory steps in synaptic neurotransmission, receptor recycling, endosomal trafficking and lysosomal degradation are controlled by relatively few proteins. Studies in neurons and brain are limited but many reciprocal connections are apparent [8]. For example, **(a)** SNCA functions with heat shock chaperone Hsc70 and SNAP25 to promote membrane SNARE complex assembly and exocytosis in neurotransmission. **(b)** In mammalian cells, LRRK2 may also regulate cleavage of invaginated endocytic membrane through interaction with dynamin. Several other genes, including *DNAJC6* (with homology to *GAK*) and *SYNJ1*, encode proteins important in clathrin uncoating. In *Drosophila*, LRK1 (the homolog of mammalian LRRK1 and LRRK2) phosphorylates endophilin A to directly regulate endocytosis. In the mammalian striatum the expression levels of SNCA and endophilin A are reciprocally related. **(c)** In the endosome, VPS35 and the retromer cargo-selective-complex (CSC; comprising VPS35-VPS26 and VPS29) play an important role in membrane protein cargo sorting. The CSC is best described in endosome to trans-Golgi network retrieval in the soma, most specifically in recycling cation-independent mannose-6-phosphate receptor that traffics acidic hydrolases (including GBA) to the lysosome. However, recent studies in neurons have revealed that VPS35 and WASH are also crucial in protein recycling **(d)** of specific synaptic receptors from early endosome to plasma membrane, and **(e)** in the V-ATPase required for lysosomal acidification. Importantly, CSC trafficking can be mediated by sorting nexin interaction with dynactin p150$^{\text{Glued}}$ (DCTN1), dynein, tau (MAPT) and microtubules, or via the WASH complex, DNAJC13 and actin polymerization. DNAJC13 was first described in endocytosis in *C. elegans*, rather than in post-endocytic trafficking, and like SNCA requires Hsc70 to function. LRRK2 has also been shown to interact with VPS35 and microtubules, and like SNCA may be intrinsically targeted to lysosomal membranes by protein motifs for chaperone-mediated autophagy. Clearance of insoluble SNCA aggregates is also mediated by the endosomal system and lysosomal degradation [153]. Several other lysosomal proteins, including ATP13A2 and ATP6AP2, have been implicated in atypical parkinsonism. EIF4G1, through mTOR regulation of protein translation, serves to balance autophagic activity and metabolism or ATP levels, whereas **(f)** PINK1 and Parkin are intrinsically involved in mitochondrial quality control in early onset parknsonism.

Recessively inherited mutations in *DNAJC6* have recently been identified in juvenile parkinsonism [70]. *DNAJC6* encodes auxilin, a homolog of cyclin-G associated kinase (GAK; Table 1), which is preferentially expressed in neurons and involved in clathrin uncoating and synaptic vesicle recycling. Similarly, recessively inherited mutations in *SYNJ1*, encoding synaptojamin, that complexes with Hsc70 and auxilin, have been implicated in disease [72].

Endosomal trafficking

Endosomal trafficking is a highly complex and dynamic cellular process whereby vesicles or cargos that are internalized at the plasma membrane are subsequently recycled, directly or via the trans-Golgi network, and targeted for degradation by lysosomal autophagy. Mutations in VPS35 and RME-8 (receptor-mediated endocytosis 8, also known as DNAJC13) were recently linked to late-onset Lewy body parkinsonism and directly implicate endosomal trafficking in disease pathogenesis [63,93]. Neurons have a critical need to recycle membrane receptors. This can be accomplished through the clathrin-independent retromer system, a tubulovesicular tripartite complex of VPS26 (vacuolar sorting protein 26), VPS29 and VPS35 that relies on sorting nexins to stipulate the destinations of specific cargos, such as neurotransmitter receptors. Multiple VPS35 subunits coalesce about FAM21, a subunit of the WASH (Wiskott-Aldrich syndrome protein and scar homolog) complex, to mediate dynamic actin remodeling [94]. RME-8 also binds sorting nexins and FAM21 to influence WASH and cargo trafficking [95]. VPS35 may also physically interact with LRRK2 and Rab7L1 (within the PM20D1 locus; Table 1) to influence these processes [96].

Lysosomal autophagy

Lysosomes have an essential function in maintaining protein and organelle integrity within cells and impaired lysosomal function may play an important role in the pathogenesis of PD. Aggregated alpha-synuclein, in the form of Lewy neuritic or Lewy body inclusions, that fails to be degraded by proteosomal or lysosomal systems is the pathologic hallmark of PD. It is presently unknown whether the intracellular protein aggregation observed in most late-onset neurodegenerative diseases is a cause or consequence of dysfunction in these pathways [97]. The formation of intracellular aggregated alpha-synuclein or tau inclusions, albeit not a primary pathology, is also found in several ceroid lipofuscinosis disorders. These include glycolipid storage diseases such as Gaucher disease and Niemann-Pick type C that are most prevalent in Ashkenazi Jewish communities. Although the *GBA* (glucocerebrosidase gene) mutations are recessively inherited in Gaucher disease, heterozygote carriers have an increased prevalence of PD and dementia with Lewy bodies (Table 1) [98]. A lysosomal pathway for parkinsonism centered around ceramide metabolism has been hypothesized [99]. Loss of GBA activity increases intracellular glucosylceramide accumulation, resulting in decreased lysosomal degradation and subsequent accumulation of alpha-synuclein [100]. Whether the latter reflects impaired GBA trafficking from the endoplasmic reticulum and Golgi to lysosomes or whether it results directly from lysosomal dysfunction is unclear. In genetically engineered mice, *GBA* mutations promote alpha-synuclein accumulation in a dose- and time-dependent manner, with the animals developing Lewy-like pathology in the brain and associated motor and cognitive phenotypes. By contrast, loss of GBA activity results in neuronal ubiquitinopathy and formation of axonal spheroids, a phenotype that is shared with other lysosomal storage disorders prior to increased alpha-synuclein concentrations [101].

Two juvenile or early-onset forms of atypical parkinsonism result directly from mutations in lysosomal proteins. X-linked parkinsonism, with onset in males between 14 and 50 years of age and associated with post-mortem tau pathology, is a consequence of splicing or protein isoform deficits in *ATP6AP2* (encoding ATPase, H^+ transporting, lysosomal accessory protein 2) [71]. Recessively inherited p*athogenic mutations in* ATP13A2 (ATPase type 13A2 gene) also result in impaired lysosomal proteolysis, leading to Kufor-Rakeb syndrome [102]. Patients and knock-out mice develop ceroid lipofuscin neuronal pathology, and the mice show concomitant upregulation of alpha-synuclein protein in the hippocampus [103]. Many genes are implicated in neurodegeneration with brain iron accumulation, including *ATP13A2*, *PLA2G6*, *PANK2*, *C19orf12*, *FA2H*, *WDR45*, *FTL*, *CP*, and *DCAF17* [104].

Mitochondrial metabolism

The earliest link between mitochondrial dysfunction and parkinsonism was observed in illicit drug users. MPTP (1-methyi-4-phenyl-1,2,3,6-tetrahydropyridine) is specifically transported into dopamine neurons via the dopamine transporter and is then oxidized into toxic MPP^+, a non-competitive complex inhibitor of the electron transport chain [105]. Deficits of mitochondrial complex I have been noted in idiopathic PD [106], although evidence from direct sequencing studies of normal brain has proven equivocal. Mitochondrial mutations in humans lead to several neuromuscular disorders [107]. While the majority are not associated with parkinsonism, similar movement disorders with or without chronic progressive ophthalmoplegia can be caused by mutations in mitochondrial DNA polymerase γ (POLG), a proofreading enzyme. Mouse models with defective POLG exhibit premature ageing whereas older homozygous, but not heterozygous, POLG mice show significant reductions in striatal dopaminergic terminals as well as deficits in motor function [108].

The importance of mitochondria in parkinsonism is highlighted by the identification of mutations in several genes within a common pathway for mitophagy. Mutations in the *PARK2* (*parkin*) gene result in a recessive form of early-onset parkinsonism [109]. Parkin protein was first described as a proteosomal E3 ubiquitin ligase responsible for K48 substrate polyubiquination (targeting to the proteosome) and K63 monoubiquination (for signaling) [110]. In addition, parkin may have several physiological roles in neurons - for example, in Eps15 monoubiquination [111] and in the regulation of neuronal apoptosis as part of a SCF-like complex [112]. Most highlighted is the role of parkin in regulating the degradation of depolarized or uncoupled mitochondria, in concert with PINK1 (Pten-induced kinase 1) and FBXO7 (F-box domain-containing protein), which are also genes implicated in recessive early-onset parkinsonism [68,113]. *Drosophila* parkin and *PINK1* knockout models exhibit similar mitochondrial and wing phenotypes, and a series of elegant experiments has demonstrated that PINK1 is required for the recruitment of parkin to mitochondria [114,115]. The crystal structure of parkin has now been solved [116] and PINK1 has been shown to phosphorylate ubiquitin required for parkin's activation [117]. Two recent RNA interference screens have identified upstream regulators of mitophagy, albeit with limited overlap [118,119]. These include TOMM7, essential for stabilizing PINK1 on the outer mitochondrial membrane; HSPA1L and BAG4, which may help to regulate parkin translocation to mitochondria; and SIAH3, which is localized to mitochondria and inhibits PINK1 after mitochondrial damage, thereby reducing parkin translocation. Hexokinase activity, occurring downstream of Akt but upstream of PINK1, may also be required in the recruitment of parkin to depolarized mitochondria [119]. STOML2, mitofusin1/2, GRP75, HSP60, LRPPRC, and TUFM have been nominated as downstream targets of the PINK1/parkin pathway [120-122]. DJ-1 mutations, which result in early-onset parkinsonism [123], may also regulate PINK1-dependent parkin translocation to depolarized mitochondria [124]. DJ-1 deficiency leads to altered mitochondrial morphology and increased levels of reactive oxygen species (ROS) [124]. Traditionally, knockout mouse models of parkin, PINK1 or DJ-1 result in mitochondrial dysfunction [125] but do not develop the locomotor phenotype of parkinsonism, nigral neuronal loss or Lewy-body pathology; rather they have elevated dopaminergic tone due to deficits in D2 presynaptic regulation of release [126,127]. However, a recent conditional parkin knockout mouse model demonstrated progressive loss of dopamine neurons in a PARIS-dependent pathway [128]. Thus, protein components of the parkin/PINK1 mitochondrial pathways remain plausible therapeutic targets for human carriers of these mutations and potentially for idiopathic PD.

While mitochondrial mutations and proteins involved in mitophagy have been directly implicated in parkinsonism, there is accumulating albeit indirect evidence that mitochondrial function is central to disease pathogenesis and/or progression. For example, alpha-synuclein overexpression may impair mitochondrial activity, thereby accumulating mitochondrial DNA damage and degeneration, ultimately resulting in neuronal death [129]. For LRRK2, mitochondrial pathology was observed in human dopaminergic neurons derived from inducible pluripotent cell lines of *LRRK2* p.G2019S carriers [130] and in aging p.G2019S transgenic mice [131]. In primary cortical neurons, overexpression of wild-type LRRK2 and of pathogenic mutant LRRK2 proteins both increased recruitment of mitochondrial dynamin-like protein to fragmenting mitochondria [132].

Conclusions and future directions

Idiopathic PD, albeit a sporadic disorder with low heritability, now appears to have a significant genetic component. Many genes have been identified and several more will probably emerge from a variety of complementary approaches. Most immediately, targeted genomic sequencing might identify functional variants in GWAS-associated loci, whereas additional GWAS in non-Caucasian populations might identify novel loci. WES in families with parkinsonism is also a pragmatic step to identify more genes using a concordant 'pairwise' approach. Ultimately, collaborative pooled analysis of exome data might facilitate association analysis; power estimates suggest that as few as 50 exomes may be sufficient to identify a novel locus for recessive disease, although 10,000 are likely to be required to identify a novel dominant gene mutation [133]. Nevertheless, segregation of rare mutations with disease and/or functional studies will be needed. Inevitably, with less penetrant variants, the results from these approaches will become increasingly difficult to interpret. Hence, rather than focusing on PD as the trait, more investment may be warranted on longitudinal studies. In addition, better characterization of trait components, such as cognition in PD, symptom progression and response to medication, would enable further genetic variability to be identified. Similar analyses in more genetically homogeneous populations (employing linkage, association and genome sequencing) and in sample series or pedigrees of sufficient size and structure may enable the joint contribution of genes and environment to be assessed meaningfully. We suggest that a genetic predisposition to PD should not be considered 'causal', rather disease reflects chronic molecular dysfunction and the failure of age-associated compensation.

To date, four biological pathways have been implicated in familial parkinsonism: synaptic neurotransmission, endosomal trafficking, lysosomal autophagy and mitochondrial metabolism. Direct interactions between genetic components and these pathways are emerging, whether *VPS35* and *RME-8* in late onset PD, or *parkin* and *PINK1* in mitophagy in early onset parkinsonism. Although the processes highlighted may be viewed separately, several employ the same protein machinery and may be temporally and functionally related. For example, synaptic dysfunction, resulting from or leading to alpha-synucleinopathy, impairs the balance of exo- and endocytosis, neurotransmission and early endosomal receptor recycling. These changes will alter flux through the endosomal pathway and ultimately place demand on autophagy and lysosomal fusion with multivesicular bodies. Many of the same proteins are involved in more than one of the four pathways; for example, VPS35 directly affects both early-endosome receptor recycling in dendritic spines and lysosomal ATPase recycling from multivesicular bodies [134]. Similarly, LRRK2 appears to be centrally involved in neurite outgrowth and in membrane protein cargo sorting and trafficking, interacts with dynamin GTPases, and may regulate endophilin phosphorylation, membrane scission and endocytosis. VPS35, RME-8 and potentially LRRK2 coordinate the WASH complex in specific actin networks underlying membrane deformation, tubulation and cargo trafficking. The caveat is that many of the biological insights may be model specific, or have yet to be performed in vertebrate systems in post-mitotic neurons or in brain.

In conclusion, genomic and genetic investigations should continue to be a main priority for future research. Knowledge of the pathogenic pathways underlying the etiology and ontology of PD clearly facilitates an understanding of common protein components and central processes that are crucial for therapeutic development. Our understanding of the normal physiology of the brain, of specific neuronal populations, protein pathways and the function of individual proteins, is rudimentary. When it comes to formulating a molecular synthesis of the pathways involved in parkinsonism, genetic insights may be unbiased and unequivocal but those insights must be carefully weighted. Genetic association is far from causation and much work is required to understand the specific contribution of GWAS, let alone to translate the information from such studies into novel treatments to slow or halt the progression of idiopathic PD. In interpreting linkage and exome studies, the phenotypes of patients and families must be carefully considered. The heterogeneity of parkinsonism is considerable and there are many forms that may not be etiologically related. Arguably, findings from familial late-onset Lewy-body parkinsonism may be more relevant to idiopathic PD than those from atypical and/or early-onset forms. Brain pathology, long required for a definite diagnosis, appears increasingly pleomorphic in genetically defined disease, even for the same mutation in the same family. Such alternative pathologic outcomes become more intriguing as specific molecular deficits in membrane protein sorting and cargo trafficking are revealed. That aggregate alpha-synuclein and tau pathologies may be seeded and transmissible throughout the cerebrum presents an attractive means to explore Braak staging (a regional and temporal scheme for the progression of these inclusion body pathologies) and vulnerable cell populations in specific genetic backgrounds. Much neuroscience in PD was derived from model systems based on toxin administration, and may not accurately reflect the human condition. Why the *substantia nigra pars compacta* is selectively lost in PD remains enigmatic, but through human genetics we now have relevant molecular targets and tools to investigate this.

With such advances, therapeutic prospects for disease modification (neuroprotection) should be viewed with more optimism [135].

Abbreviations

ATP13A2: ATPase type 13A2 gene; ATP6AP2: ATPase, H^+ transporting, lysosomal accessory protein 2; CSC: cargo-selective-complex; DBS: deep brain stimulation; EIF4G1: elongation initiation factor 4 gamma 1; FBXO7: F-box domain-containing protein 7; FTDP-17: frontotemporal dementia with parkinsonism linked to chromosome 17; GAK: cyclin-G associated kinase; *GBA*: glucocerebrosidease gene; GWAS: genome-wide association study; H&E staining: hematoxylin and eosin staining; LRRK2: leucine-rich repeat kinase 2 protein; MAPT: microtubule-associated protein tau; MPTP: 1-methyi-4-phenyl-1,2,3,6-tetrahydropyridine; NACP: non-amyloid component of plaques; NGS: next-generation sequencing; OMIM: Online Mendelian Inheritance in Man; PD: Parkinson's disease; POLG: DNA polymerase γ; RME-8: receptor-mediated endocytosis 8; ROS: reactive oxygen species; SN: *substantial nigra pars compacta*; *SNCA*: alpha-synuclein gene; SNP: single nucleotide polymorphism; UCHL1: Ubiquitin C-terminal hydrolase1; UTR: untranslated region; VPS35: vacuolar sorting protein 35; WASH: Wiskott-Aldrich syndrome protein and scar homolog; WES: whole-exome sequencing; WGS: whole-genome sequencing.

Competing interests

The authors declare that they have no competing interests.

Acknowledgements

We are indebted to the Canada Excellence Research Chairs program and the Dr Donald Rix BC Leadership Chair in Genetic Medicine for ongoing support of the Centre of Applied Neurogenetics and Translational Neuroscience.

Population genomics and antimicrobial resistance in *Corynebacterium diphtheriae*

Melanie Hennart[1,2], Leonardo G. Panunzi[1,3], Carla Rodrigues[1], Quentin Gaday[4], Sarah L. Baines[5], Marina Barros-Pinkelnig[1], Annick Carmi-Leroy[1,6], Melody Dazas[1,6], Anne Marie Wehenkel[4], Xavier Didelot[7], Julie Toubiana[1,6,8], Edgar Badell[1,6] and Sylvain Brisse[1,6*]

Abstract

Background: *Corynebacterium diphtheriae*, the agent of diphtheria, is a genetically diverse bacterial species. Although antimicrobial resistance has emerged against several drugs including first-line penicillin, the genomic determinants and population dynamics of resistance are largely unknown for this neglected human pathogen.

Methods: Here, we analyzed the associations of antimicrobial susceptibility phenotypes, diphtheria toxin production, and genomic features in *C. diphtheriae*. We used 247 strains collected over several decades in multiple world regions, including the 163 clinical isolates collected prospectively from 2008 to 2017 in France mainland and overseas territories.

Results: Phylogenetic analysis revealed multiple deep-branching sublineages, grouped into a Mitis lineage strongly associated with diphtheria toxin production and a largely toxin gene-negative Gravis lineage with few toxin-producing isolates including the 1990s ex-Soviet Union outbreak strain. The distribution of susceptibility phenotypes allowed proposing ecological cutoffs for most of the 19 agents tested, thereby defining acquired antimicrobial resistance. Penicillin resistance was found in 17.2% of prospective isolates. Seventeen (10.4%) prospective isolates were multidrug-resistant (≥ 3 antimicrobial categories), including four isolates resistant to penicillin and macrolides. Homologous recombination was frequent (r/m = 5), and horizontal gene transfer contributed to the emergence of antimicrobial resistance in multiple sublineages. Genome-wide association mapping uncovered genetic factors of resistance, including an accessory penicillin-binding protein (PBP2m) located in diverse genomic contexts. Gene *pbp2m* is widespread in other *Corynebacterium* species, and its expression in *C. glutamicum* demonstrated its effect against several beta-lactams. A novel 73-kb *C. diphtheriae* multiresistance plasmid was discovered.

Conclusions: This work uncovers the dynamics of antimicrobial resistance in *C. diphtheriae* in the context of phylogenetic structure, biovar, and diphtheria toxin production and provides a blueprint to analyze re-emerging diphtheria.

Background

Diphtheria, if untreated, is one of the most severe bacterial infections of humans. It typically affects the upper respiratory tract causing pseudomembrane formation, sometimes leading to suffocation and death. The infection can be complicated by systemic symptoms, caused by the diphtheria toxin. Other forms of disease are skin and invasive infections, including endocarditis [1, 2].

The agent of diphtheria is *Corynebacterium diphtheriae*, a member of the phylum Actinomycetes [3, 4]. The diphtheria toxin, encoded by the *tox* gene, is carried by lysogenized corynephages within the chromosome of some *C. diphtheriae* strains [5, 6]. Concern exists about the possibility of lysogenic conversion of previously non-toxigenic strains during colonization, infection, or transmission chains [7]. However, knowledge on the microevolutionary dynamics between *tox*-positive and *tox*-negative strains is limited. The high genetic diversity of *C. diphtheriae* strains underlies their variable colonization, adhesion, and pathogenicity properties [8–10]. Although three main biovars (Mitis, Gravis, and Belfanti) are distinguished since the 1950s, their phylogenetic relationships are poorly defined [11–13].

Diphtheria used to be one of the deadliest infections in young children but has been largely controlled by vaccination with the highly effective toxoid vaccine [14]. Even so, thousands of cases of diphtheria are still reported annually [15], and large outbreaks can quickly follow the disruption of public health systems [14, 16–18]. In countries with high vaccination coverage, diphtheria cases are associated with travel and migration from endemic regions [19–21]. As diphtheria vaccination is performed using an inactivated form of diphtheria toxin, it is not considered to prevent asymptomatic colonization and silent transmission of the pathogen, which still circulates and is the object of intense epidemiological surveillance [4]. However, vaccine preparations may include other antigens, and the impact of vaccination on *C. diphtheriae* evolution deserves further studies [22].

Clinical management of infections with toxigenic isolates includes treatment with diphtheria antitoxin (DAT), which can prevent or reduce the systemic effects of the toxin [4]. Nevertheless, antimicrobial treatment is critical in the clinical management of both *tox*-positive and *tox*-negative infections, as it contributes to the elimination of the bacteria within the patient and limits transmission to novel individuals [23]. With DAT production being threatened [24], antimicrobial treatment might become even more critical in diphtheria therapy.

Penicillin is the first-line therapeutics to treat diphtheria, with erythromycin being recommended in case of allergy [25]. Both antimicrobial agents are generally effective for the treatment of diphtheria [23, 26]. However, reduced susceptibility or full resistance of *C. diphtheriae* to penicillin, erythromycin, and other antimicrobial agents, sometimes combined in multidrug-resistant strains, has been reported from multiple world regions [23, 26–35].

Antimicrobial resistance genes have been described in *C. diphtheriae*, including the erythromycin resistance gene *ermX* on plasmid pNG2 [36] and genes *dfrA16*, *qacH*, and *sul1* carried on a class 1 integron, mobilized by IS*6100* [37]. However, the prevalence and phylogenetic distribution of resistance genes in *C. diphtheriae* clinical isolates are unknown. Six chromosomal penicillin-binding proteins (PBPs) have been reported in *C. diphtheriae* [38], but so far, no association between *pbp* or other genetic variation and penicillin resistance has been described. Understanding the genetic basis of antimicrobial resistance in *C. diphtheriae* would improve our ability to diagnose and track its spread.

The aims of this study were (i) to characterize antimicrobial resistance phenotypes in a large collection of *C. diphtheriae* strains with diverse geographical and temporal origins and to uncover genomic determinants of resistance and (ii) to analyze the population structure of *C. diphtheriae* and define the associations between antimicrobial resistance, diphtheria toxin production, biovars, and phylogenetic sublineages.

Methods

Corynebacterium diphtheriae isolates and strains

A collection of 247 *C. diphtheriae* isolates were included (Additional file 1: Table S1), corresponding to three subsets. First, we included 163 clinical isolates (recent clinical isolates subset, Additional file 1: Table S1) collected prospectively between 2008 and 2017 by the French National Reference Center for Corynebacteria of the *Corynebacterium diphtheriae* complex (NRC-CCD). These isolates represented all isolates received at the NRC-CCD that corresponded to the *C. diphtheriae* species (*C. belfantii*, *C. ulcerans*, *C. pseudotuberculosis*, or other corynebacteria were excluded). They were collected from cutaneous (*n* = 136), respiratory (*n* = 23), and other (bones, blood; *n* = 4) infections. Of these, 74 were from Mainland France and 89 from French overseas territories, including Mayotte (*n* = 50), New Caledonia (*n* = 19), La Réunion Island (*n* = 11), French Guiana (*n* = 4), French Polynesia (*n* = 3), and Guadeloupe (*n* = 1); one isolate received from Institut Pasteur in Madagascar was also included (Fig. 1). Four isolates from New Caledonia collected between 2002 and 2006 (02-0322, 02-0338, 03-1641, and 06-1569) were included in a previous study [39]; the trimethoprim- and sulfamethoxazole-resistant isolate FRC0024 was previously shown to harbor an integron with gene *drfA16* [37].

Second, we included 15 clinical isolates collected in France between 1981 and 1991, 11 of which had been deposited in the Collection de l'Institut Pasteur (CIP;

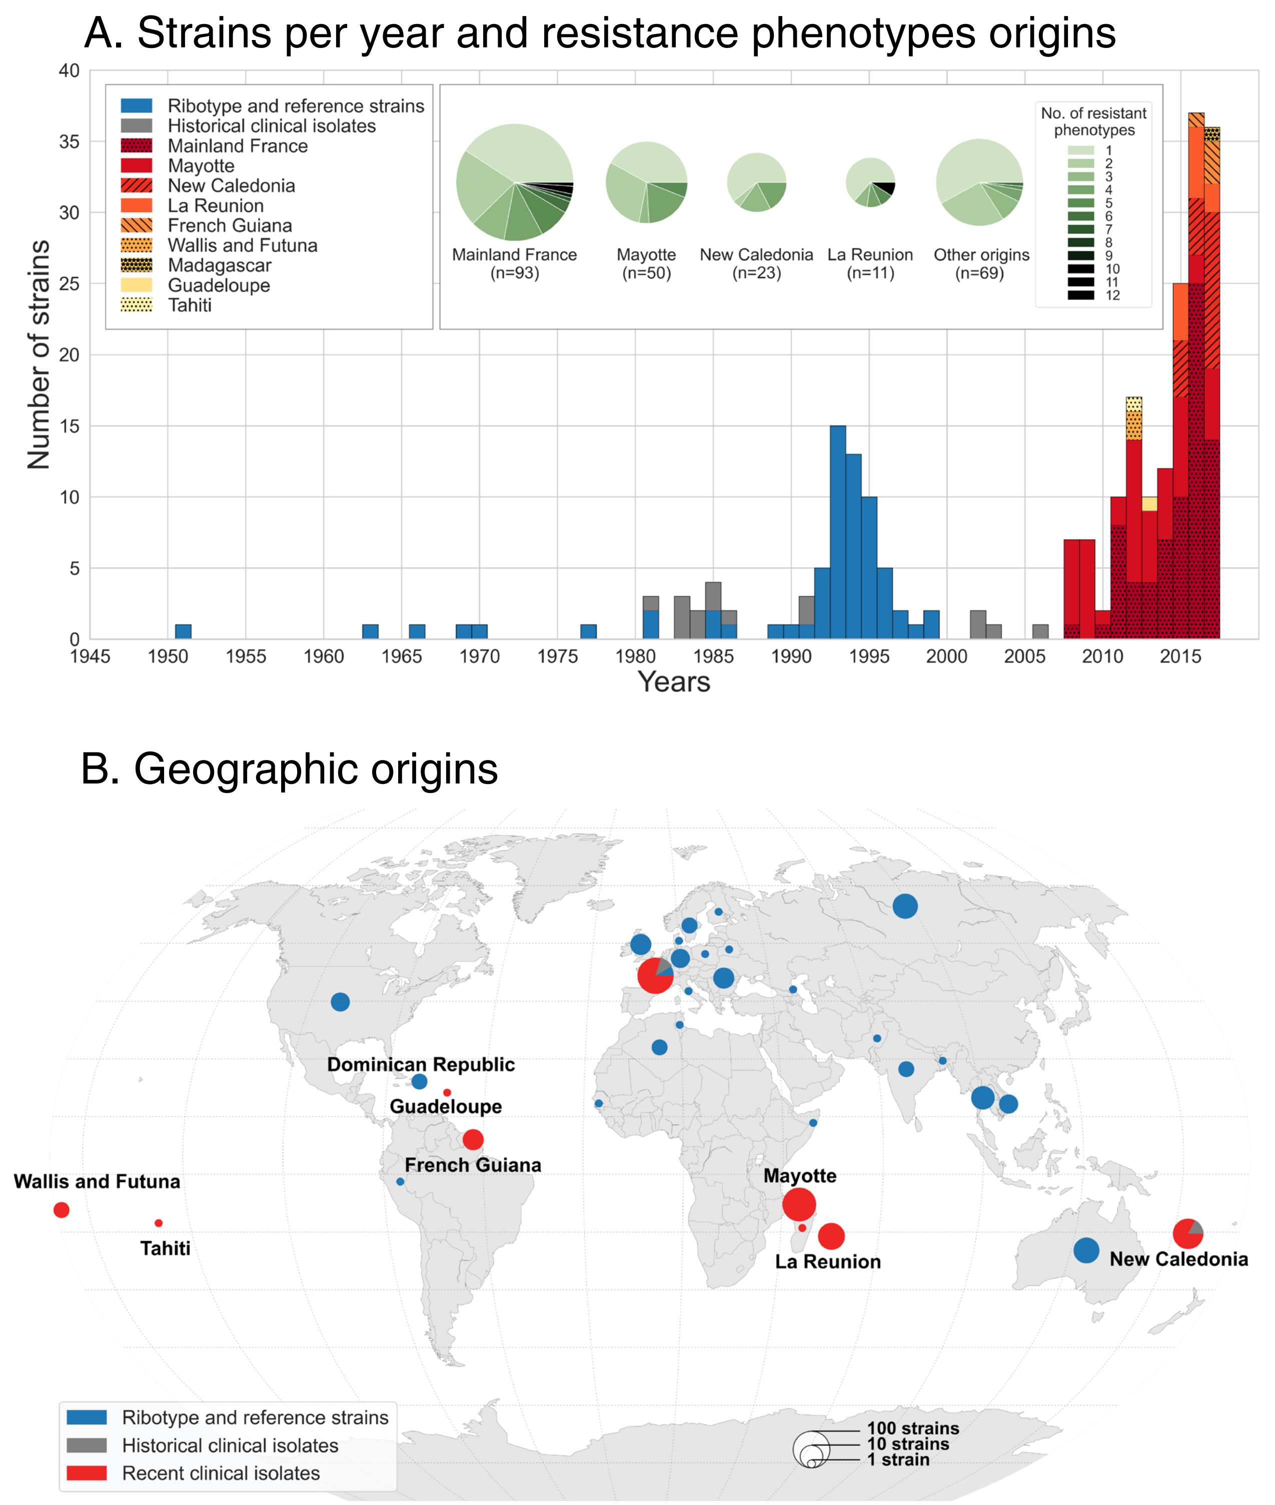

Fig. 1 Temporal and geographical distribution of strains studied. **a** The number of strains per year, 1945–2017. The 2008–2017 clinical isolates are represented in red- or yellow-shaded patterns (see key), whereas the older clinical isolates are in gray and the reference strains in blue. The inset shows the pie charts with the frequency of resistance phenotypes among strains from the four most represented geographic origins; the remaining ones are pooled in the right-most pie chart. **b** Geographic origins of strains from the three subsets

historical clinical isolates subset in Additional file 1: Table S1).

Third, to increase the genetic diversity and geographic range of the sample, the 65 available reference strains of ribotypes that belong to *C. diphtheriae* were included [40]. These reference strains represent an international collection of isolates collected over several decades and originating from multiple world regions including the Americas, Europe, Asia, Africa, and Oceania. Our subcultures of these strains were controlled for *tox* gene presence, toxin production, and biovar, leading to modifications of published characteristics in some instances (Additional file 1: Table S1; Fig. 1). Finally, four reference strains were included: strain NCTC13129, which is used as genomic sequence reference [38]; strain NCTC10648, which is used as the *tox*-positive and toxinogenic reference strain in PCR and Elek tests, respectively; strain NCTC11397^{T}, which is the taxonomic type strain of the *C. diphtheriae* species; and the vaccine production strain PW8, which corresponds to CIP A102 [41]. This third subset is referred to as "ribotype and reference strains" subset (Additional file 1: Table S1).

Bacterial cultures, identification, and biovar

Bacteria were cultivated on Trypto-Casein-Soy (TCS) agar for 24 h at 35–37 °C. Bacterial identification was performed at the NRC-CCD as described previously [42] by multiplex polymerase chain reaction (PCR) combining a *dtxR* gene fragment specific for *C. diphtheriae* and a multiplex PCR that targets a fragment of the *pld* gene specific for *C. pseudotuberculosis*, the gene *rpoB* (amplified in all species of the *C. diphtheriae* complex) and a fragment of 16S rRNA gene specific for *C. pseudotuberculosis* and *C. ulcerans*, respectively. Isolates collected since 2014 were confirmed as *C. diphtheriae* by matrix-assisted laser desorption-ionization time-of-flight mass spectrometry (MALDI-TOF MS) using Bruker technology. In order to exclude strains initially identified as *C. diphtheriae* but now classified as *C. belfantii* [42] or *C. rouxii* [43], genome-wide average nucleotide identity (ANI) was used as described previously [42]. Strains were characterized biochemically for pyrazinamidase, urease, and nitrate reductase and for utilization of maltose and trehalose using API Coryne strips (BioMérieux, Marcy l'Etoile, France) and the Rosco Diagnostica reagents (Eurobio, Les Ulis, France). The Hiss serum water test was used for glycogen fermentation. The biovar of isolates was determined based on the combination of nitrate reductase (positive in Mitis and Gravis, negative in Belfanti) and glycogen fermentation (positive in Gravis only). The rare biovar Intermedius was not identified, as its distinction from other biovars is based on colony morphology, which is considered subjective, or on lipophily, which was not tested.

Determination of the presence of the *tox* gene

Determination of the diphtheria toxin gene (*tox* gene) presence was achieved by a conventional *tox* PCR assay [44], while its phenotypic production was assessed by the modified Elek test [45]. We also confirmed *tox* PCR results by BLASTN (query: *tox* gene sequence from strain NCTC13129, RefSeq accession number: DIP_RS12515) analysis of the genomic assemblies.

Antimicrobial susceptibility testing

Phenotypic susceptibility was tested for the following agents: penicillin G (10 IU), amoxicillin, oxacillin, cefotaxime, imipenem, erythromycin, azithromycin, clarithromycin, spiramycin, pristinamycin, kanamycin, gentamicin, rifampicin, tetracycline, ciprofloxacin, clindamycin, sulfonamide, trimethoprim, and trimethoprim + sulfamethoxazole. The 19 antimicrobial agents tested (Table S1) corresponded to seven classes, as described hereafter: *β*-lactams: penicillin G (PEN), amoxicillin (AMX), oxacillin (OXA), cefotaxime (CFT), imipenem (IMP); macrolides: azithromycin (AZM), clarithromycin (CLR), erythromycin (ERT), and spiramycin (SPR); lincosamides: clindamycin (CLD); streptogramins: pristinamycin (PRT); aminoglycosides: gentamicin (GEN) and kanamycin (KAN); folate pathway inhibitors: sulfonamide (SUL), trimethoprim (TMP), and trimethoprim + sulfamethoxazole (cotrimoxazole, TMP-STX); ansamycins: rifampicin (RIF); tetracyclines: tetracycline (TET); and fluoroquinolones: ciprofloxacin (CIP).

Antimicrobial susceptibility was determined using the disk diffusion method with impregnated paper disks (Bio-Rad, Marnes-la-Coquette, France) on Mueller Hinton agar plates supplemented with 5% of sheep blood and 20 mg/L β-NAD, as recommended. Minimum inhibitory concentrations (MICs) were determined using E-test strips (BioMerieux, Marcy l'Etoile, France). The control strain used is *Streptococcus pneumoniae* ATCC 49619. The zone diameter (ZD) data were interpreted into S, I, and R categories in the following way. First, we used the CA-SFM/EUCAST V.1.0 (January 2019) document (https://www.sfm-microbiologie.org/wp-content/uploads/2019/02/CASFM2019_V1.0.pdf), which contains interpretative criteria for *Corynebacterium* spp. only for CIP, GEN, CLD, TET, RIF, and TMP-STX. Second, for the other agents, we used the interpretative criteria published in Table III of the CA-SFM 2013 recommendations (https://resapath.anses.fr/resapath_uploadfiles/files/Documents/2013_CASFM.pdf). Note that for RIF, we used the 2013 breakpoints, as they fitted better with the observed distribution of ZD values. Clarithromycin breakpoints were taken from those for erythromycin, as recommended. The breakpoint for oxacillin was derived from the one used for *Staphylococcus* spp. ZD interpretation breakpoints are given in Additional file 1: Table S2.

Penicillin susceptibility was initially determined using 10-UI (6 μg) disks (resistance breakpoint, 18 mm), but CA-SFM/EUCAST recommendations were changed in 2014 to use 1-UI disks, while the resistance breakpoint was increased from 18 to 29 mm. As all *C. diphtheriae* strains end up in the resistant category following this recommendation, E-test strips were used to define the penicillin MIC since 2014 (Additional file 1: Table S2: isolates starting from FRC0259); the EUCAST breakpoint of 0.125 g/L was used as a cutoff. Penicillin E-test was also performed systematically for strains tested as resistant before 2014 (using 10-UI disks), as well as for some susceptible isolates (Additional file 1: Table S1).

Multidrug-resistant *C. diphtheriae* (MDR-DIP) were defined as strains resistant to three or more antimicrobial agent categories (defined in Additional file 1: Table S2), excluding intrinsic resistance to fosfomycin [46]. Note that we used ecological cutoffs rather than currently proposed clinical breakpoints (see Additional file 1: Table S2 for a comparison of both types of breakpoints).

Whole-genome sequencing by Illumina and Oxford Nanopore Technologies

DNA was extracted from broth cultures, by making use of DNeasy Blood & Tissue Kit (QIAGEN, Hilden, Germany). However, a lysis step was added to the extraction protocol described by the manufacturer as previously described [47]: a 1-μL loopful of bacterial colonies was emulsified in 180 μL of lysis buffer containing 20 mM Tris-HCl, pH 8, 2 mM EDTA, 1.2% Triton X-100, and 20 mg/mL lysozyme, in a DNase/RNase-free 1.5-mL Eppendorf tube and incubated in a heating block at 37 °C for 1 h, with mixing every 20 min. After extraction, DNA concentration was measured with the Qubit 3.0 Fluorometer (Invitrogen), employing the Qubit dsDNA BR Assay Kit (Invitrogen). Besides, the DNA quality was verified using a D-One spectrophotometer (Nanodrop). Multiplexed paired-end libraries (2 × 150 bp) were prepared using the Nextera XT DNA kit (Illumina, San Diego, CA, USA) and eventually sequenced with an Illumina NextSeq-500 instrument at a minimum of 50× coverage depth. Trimming and clipping were performed using AlienTrimmer v0.4.0 [48]. Redundant or over-represented reads were reduced using the khmer software package v1.3 [49]. Finally, sequencing errors were corrected using Musket v1.1 [50]. A de novo assembly was performed for each strain using SPAdes v3.12.0 [51]. The genomic sequences of the four reference strains were retrieved from public repositories (Additional file 1: Table S1).

Additionally, the multidrug-resistant isolate FRC0402 was subjected to long-read sequencing using Oxford Nanopore Technologies (ONT). Genomic DNA was extracted using the phenol-chloroform protocol combined with Phase Lock Gel tubes (Qiagen GmbH). Libraries were prepared using a 1D ligation sequencing kit (SQK-LSK-108) without fragmentation and sequenced using a MinION FLO-MIN-106 flow cell. Finally, ONT and Illumina short reads were combined to generate a hybrid assembly using Unicycler v0.4.4 (normal assembly mode, default parameters).

Phylogeny, recombination, and genomic sequence analyses

We built a core genome multiple sequence alignment (cg-MSA) from the assembled genome sequences. For this, the genome sequences were annotated using PROKKA v1.14.2 [52] with default parameters, resulting in GFF files. Roary v3.6 [53] was used to define protein-coding gene clusters, with a threshold set at 70% amino acid identity. Core genes were defined as being present in 95% of genomes and were concatenated into a cg-MSA by Roary. ClonalFrameML v1.11 [54] was used to build a phylogenetic tree based on the cg-MSA, which quantifies and accounts for the effects of recombination events. PhyML v20131022 [55] was used to build an initial tree. To evaluate bootstrap support, IQtree version 2 [56] with best-fit model GTR+F+R10 was used.

We used Kleborate v1.0.0-beta (https://github.com/katholt/Kleborate), with the --resistance option, to identify (identity > 80% and coverage > 90%) known resistance genes in *C. diphtheriae* genomic sequences, based on the August 1, 2019, update of the ARG-Annot database. We used BLASTN (identity > 80% and coverage > 95%) to search for the presence of the *tox* gene and of genes associated with biovar Gravis (DIP351, DIP354, and DIP357) and for nitrate utilization (*narKGHJI*).

MLST genotypes were defined using the international MLST scheme for *C. diphtheriae* and *C. ulcerans* [12].

Genome-wide association studies

The software treeWAS [57] was used to find genome-wide associations between either antimicrobial resistance phenotypes or biovar on the one hand and genetic variants (both core-genome SNPs and accessory genome gene presence/absence) on the other hand. Core-genome SNPs were derived either from a mapping approach (Samtools v1.9 and GATK v3.4-0), which comprises intergenic regions, or from the alignment of core coding sequences found using Roary. We ran treeWAS v1.1 with default parameters, using as input the previously computed ClonalFrameML phylogenetic tree and distribution of homoplasies, in order to account for both the population structure and effect of recombination. For this analysis, susceptibility phenotypes were classified into resistant or susceptible categories based on zone diameter phenotypes using the CA-SFM/EUCAST 2019 cutoffs (Fig. 3, Additional file 3: Table S3). The seven chromosomal PBP coding sequences (including gene with locus tag RS14485 in RefSeq NC_002935.2, or DIP0637 in the original GenBank file, renamed by us as PBP4b) were extracted from the genomic sequences and translated into amino acid (AA) sequences, which were also analyzed for association with penicillin resistance.

Cloning and transformation experiments

For ectopic expression in *C. glutamicum*, the *pbp2m* gene was amplified from *C. diphtheriae* strain FRC0402 and put under the control of the inducible P_{gntK} promoter on the shuttle vector pTGR5 [58] (Additional file 4: Fig. S1). *pbp2m* was assembled in this plasmid by Gibson assembly using the primers PBPdi_Fw (CAA AGA AAG GAT AAG ACC ATA TGA TGA CTA AGC ACA ATC GTT TCC GTC), PBPdi_Rv (TAC CTT AAG CGG CCG CTT TAT TGA ATT CCA GAG AAT TTC TGA ACA TCC G), pTGRdi_Fw (TAA AGC GGC CGC TTA AGG TAC C), and pTGRdi_Rv (ATG GTC TTA TCC TTT CTT TGG TGG CG).

Escherichia coli CopyCutter EPI400 (Lucigen) was used for the cloning of the *pbp2m* gene and was grown in Luria-Bertani (LB) broth or agar plates at 37 °C supplemented with 50 μg/mL kanamycin. The pTGR5_pbp2m plasmid was sequenced and electroporated into *Corynebacterium glutamicum* ATCC 13032. Positive colonies were grown in brain heart infusion (BHI) at 30 °C and 120 rpm supplemented with 25 μg/mL kanamycin and 1% (w/v) gluconate when required for ectopic expression of Pbp2m.

Mapping of SNPs on *C. diphtheriae* PBP sequences

Functional annotation of the different sequences was performed with InterPro [59]. Conserved transpeptidation motifs SxxK, SxN, and KTG were identified and mapped on the PBP sequences from *Corynebacteriales* based on the results of multiple sequence alignments performed with Clustal Omega [60]. When uncertainty between a transmembrane domain and a signal peptide existed, a decision was made based on the previous characterization of the homologous PBP in other *Corynebacteriales* in the literature.

Results

Provenance and microbiological characteristics of *C. diphtheriae* isolates

We studied 247 *C. diphtheriae* strains of diverse geographic and temporal origins (Fig. 1). This collection included 163 isolates prospectively collected between 2008 and 2017 from French mainland and overseas territories, 15 older (1981–2006) French clinical isolates, 65 ribotype reference strains [40], and 4 other reference strains. All isolates were confirmed as *C. diphtheriae* (excluding *C. belfantii* and *C. rouxii*) based on an average nucleotide identity (ANI) value higher than 96% with the *C. diphtheriae* type strain NCTC11397^{T}.

Approximately one third ($n = 78$, 32%) of isolates were *tox*-positive (as defined by the detection of the *tox* gene by PCR), whereas the remaining 169 isolates (68%) were *tox*-negative. The proportions of *tox*-positive isolates were 42%, 34%, and 2% among reference strains, 2008–2017 clinical isolates, and older clinical isolates, respectively (Additional file 4: Fig. S2). Of the 78 *tox*-positive isolates, 17 (21.8%) were negative for toxin production and thus correspond to non-toxigenic toxin gene-bearing (NTTB) isolates. Six of the NTTB isolates had a stop codon within the *tox* gene sequence (Additional file 1: Table S1, Additional file 5: Table S4). However, for the 11 remaining strains, we found no explanation for the observed lack of toxin production.

Upon biotyping, 154 (62.3%) isolates belonged to biovar Mitis, 87 to biovar Gravis (35.2%), and 6 (2.4%) to biovar Belfanti (Additional file 1: Table S1). Biovar proportions were similar among the three datasets. Mitis isolates were more frequently *tox*-positive than Gravis isolates (56/154 versus 18/87, chi-squared test, *p* value 0.01; Additional file 4: Fig. S2). Among *tox*-positive isolates, NTTB were more frequent among Mitis isolates (13/56, 23.2%) than among Gravis isolates (1/18, 5.6%) although this difference was not statistically significant (*p* value 0.09). Three out of four *tox*-positive Belfanti isolates were NTTB.

Phylogenetic structure of *C. diphtheriae* and distribution of the toxin gene

To infer a phylogenetic tree, we first aimed to detect and remove homologous recombination events among *C. diphtheriae* genomic sequences. ClonalFrameML inferred a relative rate of recombination to mutation (*R*/theta) of 0.86, with an average length of recombination segments (delta) of 287 bp. The mean genetic distance between donor and recipient of recombination (nu) was estimated by ClonalFrameML to be 0.02, resulting in a relative impact of recombination to mutation in genomic diversification (r/m = *R*/theta × delta × nu) of 5.01 [61].

The recombination-corrected phylogeny was similar to the uncorrected phylogeny but with shorter branches, as expected (Additional file 4: Fig. S3). The phylogeny, rooted with *C. belfantii* and *C. rouxii* (Additional file 4: Fig. S4), was star-like, with a multitude of sublineages branching off deeply. The deepest branching sublineages corresponded to two ribotype reference strains of biovar Mitis: CIP107521 (ribotype Dagestan) and CIP107534 (ribotype Kaliningrad). Remarkably, isolates of biovars Mitis and Gravis were mostly distributed in two distinct branches of the tree. We therefore named the two major branches, lineage Mitis (156 strains, of which 86% were of biovar Mitis) and lineage Gravis (91 strains, of which

77% were of biovar Gravis). The Gravis lineage branched off from within the Mitis lineage (Fig. 2; Additional file 4: Fig. S5). However, although most shallow branches were strongly supported, bootstrap support values of the deep nodes of the phylogeny were generally weak, implying that the position of the Gravis branch within the Mitis diversity was uncertain, as were the relative positions of the early-branching Gravis and Mitis sublineages (Additional file 4: Fig. S5, Fig. S6). Reference strains PW8 and NCTC11297^T belonged to the Mitis lineage, whereas NCTC13129 (from the ex-Soviet Union 1990's outbreak) and NCTC10648 belonged to the Gravis lineage. The Belfanti isolates were scattered in three distinct sublineages within the Mitis lineage and one within the Gravis lineage.

The isolates carrying the *tox* gene belonged mostly to the Mitis lineage (68 of 78, 87.2%), in which they were distributed in multiple sublineages. In the Mitis lineage, 69 (44.2%) were *tox*-positive. In contrast, within the Gravis lineage, only 10 (11%) isolates were *tox*-positive, and they corresponded to the earliest-branching Gravis sublineages with only one exception. Interestingly, this exception corresponded to the large ex-Soviet Union outbreak in the 1990s ((Fig. 2; Additional file 4: Fig. S5). This phylogenetic pattern is consistent with an evolutionary scenario where Mitis is the ancestral biovar of *C. diphtheriae* and where Gravis evolved from the Mitis lineage as an initially *tox*-positive sublineage, with subsequent loss of the toxin gene. In this scenario, the ex-Soviet Union outbreak sublineage would have reacquired the *tox* gene. All NTTB isolates belonged to the Mitis lineage except strain CIPA99 (ribotype Rhone, biovar Belfanti; Fig. 2), and they were distributed in multiple sublineages, showing convergent evolution towards the loss of toxin production.

Genetic events linked to biovar status

Biovar Mitis and Gravis are distinguished by the ability to utilize glycogen (positive in Gravis, negative in Mitis). The *spuA* gene, which codes for a putative alpha-1,6-glycosidase, was reported as being specific for biovar Gravis isolates [62]. Our genome-wide association study (GWAS) of accessory genes with the biovar phenotype revealed a strong association of a cluster of genes that includes *spuA* (DIP357; Additional file 4: Fig. S7) with biovar Gravis isolates, providing statistical support to the discovery of Santos et al. [62]. This association was stronger within the Gravis lineage; in contrast within the Mitis lineage, few (5 out of 17) of the biovar Gravis isolates possessed *spuA* (Fig. 2). GWAS analysis of core SNPs further demonstrated that a SNP (at position 324,487, Additional file 4: Fig. S7) downstream of the *spuA* cluster insertion point was also associated with biovar, suggesting homologous recombination among core genes as a mechanism for the *spuA* cluster insertion event.

The nitrate reductase activity differentiates Mitis and Gravis isolates, which are positive, from Belfanti isolates, which are nitrate-negative. We found that the nitrate reduction *narKGHJI* gene cluster [62] was disrupted in three of the six isolates assigned to the biovar Belfanti: strains FRC0480 and FRC0481 had a G to A mutation at position 675 of the *narG* gene, leading to a stop codon, whereas in strain CIPA99, approximately 100 nucleotides were inserted at position 446 in *narG*. No molecular explanation was found for the lack of nitrate reductase ability of the three other Belfanti strains when scrutinizing the *narKGHJI* gene cluster and adjacent molybdenum cofactor biosynthesis genes [63].

Antimicrobial susceptibility variation

Susceptibility to 19 antimicrobial agents was determined for the 247 clinical isolates and reference strains (Additional file 3: Table S3). For each agent, the distribution of zone diameter (ZD) values (Fig. 3) revealed a predominant mode located towards the right end of the distribution. This mode likely corresponds to the natural susceptibility distribution within the *C. diphtheriae* population and was used to define tentative epidemiological cutoffs (ECOFFs, also called ecological cutoff [64]). The proposed ECOFFs and their comparison with clinical breakpoints are presented in Additional file 2: Table S2. For each antimicrobial agent except cefotaxime, this approach led to the identification of strains that had ZD values smaller than those in the main mode, thus potentially corresponding to acquired resistance (Fig. 3).

Penicillin was exceptional in that the predominant mode (centered around 36 mm) was less neatly defined, due to the partial overlap with a second mode of smaller diameter values centered around 24 mm. This second mode corresponds mostly to the "intermediate" interpretative category ($18 \le ZD < 29$ mm) but also overlaps with the "resistant" category (< 18 mm). The distribution of ZD values for tetracycline also showed a clear second mode. For multiple other agents (amoxicillin, oxacillin, imipenem, kanamycin, rifampicin, ciprofloxacin, clindamycin and more evidently sulfonamide, trimethoprim, and the trimethoprim-sulfamethoxazole combination), some strains had the minimal diameter (6 mm, corresponding to growth at the disk contact). For trimethoprim, we observed both a second mode centered around 14 mm and a group of even more resistant strains with growth at disk contact.

Antimicrobial resistance levels were similarly distributed between *tox*-positive and *tox*-negative isolates (Additional file 4: Fig. S8) as well as between the two main phylogenetic lineages or biovars (Additional file 4: Fig. S9; Additional file 1: Table S1). In particular, the

Fig. 2 Phylogenetic tree of *C. diphtheriae*. The tree was obtained using ClonalFrameML and was rooted using *C. rouxii* and *C. belfantii* isolates (see supplementary material). The main lineages Mitis and Gravis are labeled, and their branches are drawn using purple and green, respectively. The first (internal) circle around the tree corresponds to the three strain subsets (red, recent clinical isolates; blue, reference strains; gray, older clinical isolates). The second circle (stars) gives the toxigenic status. The third circle corresponds to biovars Mitis (purple), Gravis (green), and Belfanti (yellow). The next three circles indicate the presence of the spuA-associated gene cluster; DIP357 = *spuA* gene. The positions of reference strains PW8, NCTC13129, and NCTC10648 are indicated. The scale bar gives the number of nucleotide substitutions per site

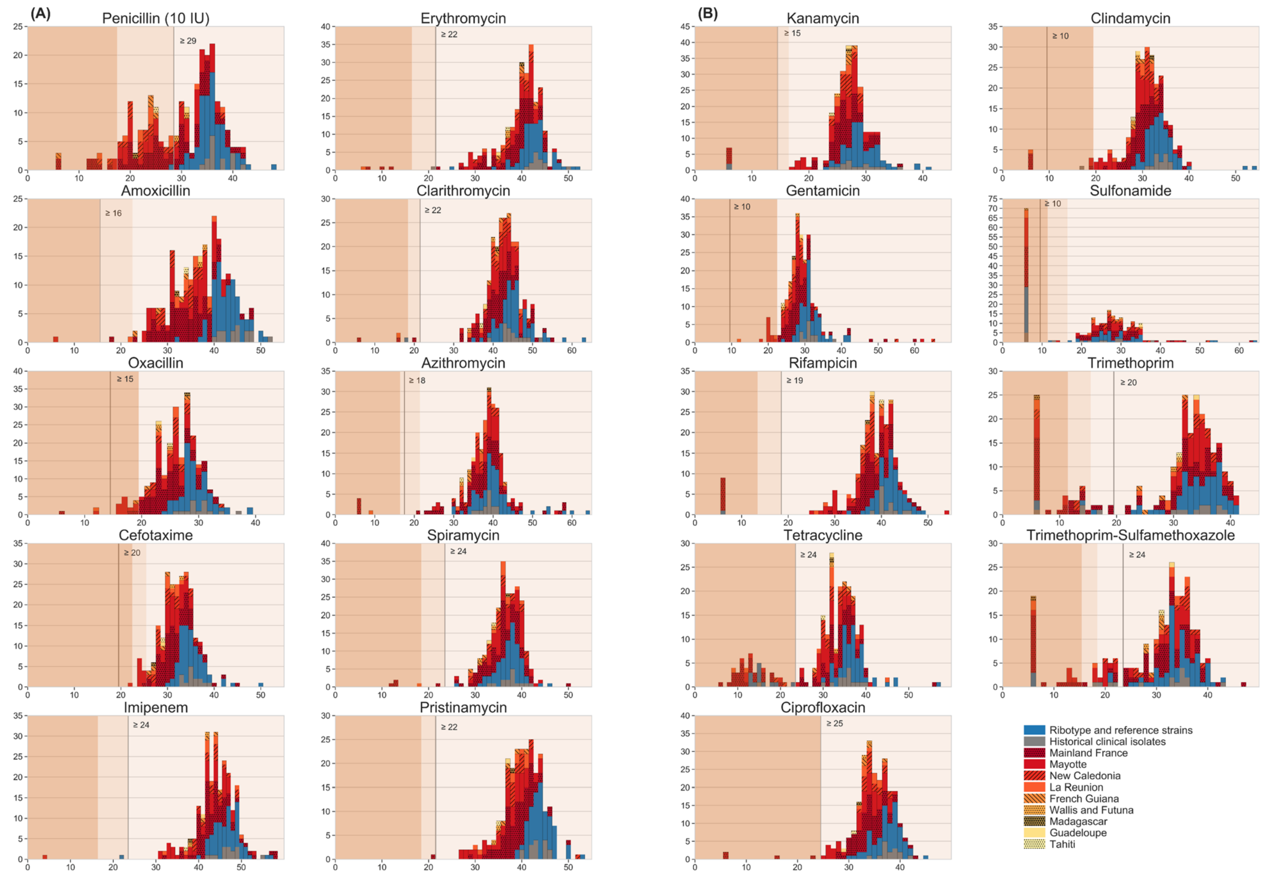

Fig. 3 The distributions of zone diameter values for 19 antimicrobial agents. **a** Beta-lactams, macrolides, and pristinamycin. **b** Other agents. *X*-axis: diameter in millimeters; *Y*-axis: number of strains. The colors inside the bars represent the subset and geographic origins as in Fig. 1 (see key on **b**). The three background colors represent the categorical interpretations according to EUCAST: resistant (salmon, left), intermediate (lighter salmon, middle), and susceptible (pale beige, right). The gray vertical bar corresponds to the proposed tentative ecological cutoff

proportion of multidrug-resistant strains was not statistically different between biovars Mitis ($n = 14$) and Gravis ($n = 4$; chi-square test p value 0.2) or between *tox*-positive and tox-negative isolates (6 versus 12, p value 0.87).

Resistance rates were 17.2%, 2.5%, and 2.5% for penicillin, amoxicillin, and erythromycin, respectively, among the prospectively collected 2008–2017 clinical isolates (Fig. 4). Reference strains were generally susceptible to most agents, including penicillin, but were partially resistant to tetracycline (18%) and sulfonamide (35%). The resistance profile distribution showed that approximately half (121/247) of the strains had a fully susceptible phenotype, whereas 18 isolates (7.3%) were multidrug-resistant (Table S1). Notably, four isolates were resistant at the same time to penicillin and macrolides (Fig. 4 inset), and two of them (FRC0402 and FRC0466) additionally had a reduced susceptibility to amoxicillin. Two of these isolates (FRC0475 and FRC0478) were collected from a foot arch wound and in respiratory carriage in the same patient (French mainland, with recent travel from New Caledonia). The two others came from a patient living in La Réunion Island (FRC0402) and from a patient living in Paris, who had recently traveled to Tunisia (FRC0466). Of the 18 multidrug-resistant isolates, 1 was a 1994 isolate from India and 17 belonged to the 2008–1017 prospective subset of clinical isolates (representing 10.4% of these). Isolates from La Réunion Island and mainland France showed resistance to multiple antimicrobial agents more often than isolates from other geographic origins (Fig. 1a, inset).

Genomic associations with antimicrobial resistance phenotypes

We first searched for the presence in the genomic sequences, of previously described antimicrobial resistance genes (ARGs). This approach led to the detection of 12 ARGs (Additional file 6: Table S5). We identified three tetracycline resistance genes (*tetW*, *tet33*, and *tetO*), four aminoglycoside resistance genes [aph (3′)-Ia, aph (3″)-Ib, aph (6)-Id, and aadA1 = ant (3′)-Ia], and also *ermX*, *dfrA16*, *dfrA15b*, *dfrA1*, and *sul1* genes. We observed a strong correlation between the presence of ARGs and the

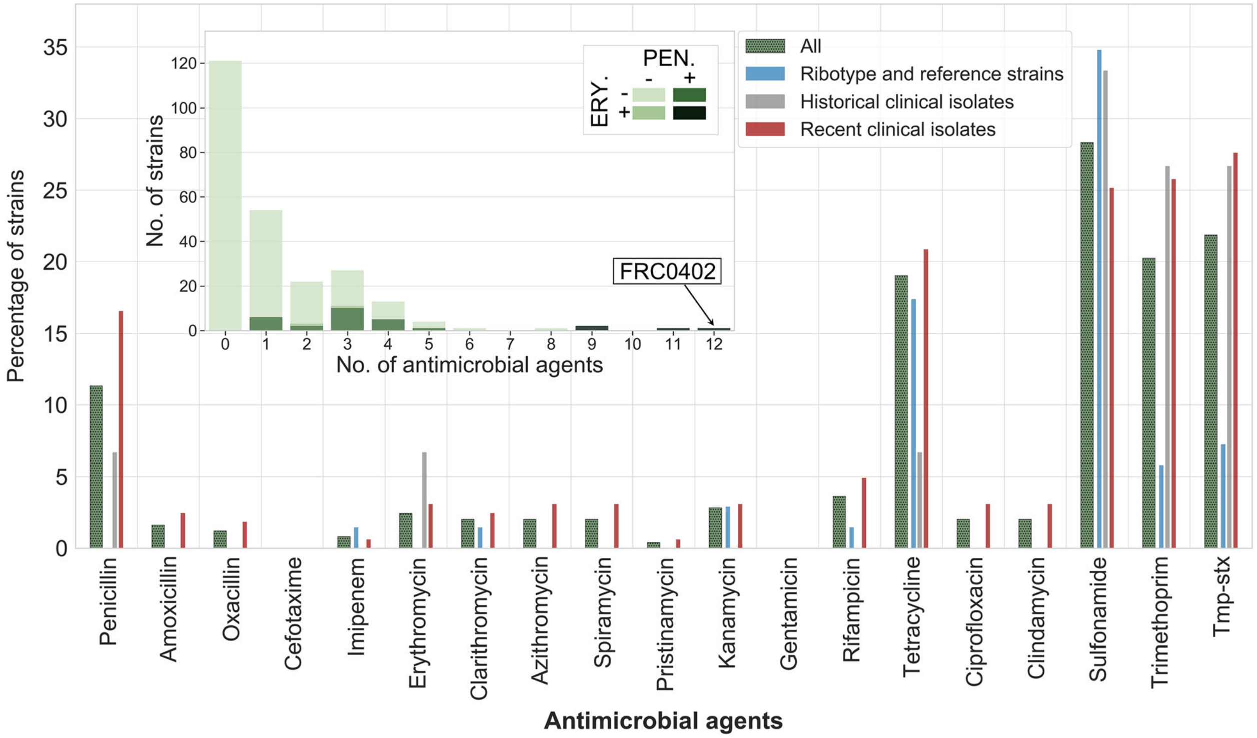

Fig. 4 Proportions of resistant strains by antimicrobial agent and multidrug resistance distribution. Interpretation of the zone diameter values was performed according to the proposed ecological cutoffs. The main panel shows the percentage of strains resistant to each agent. Tmp-stx, trimethoprim-sulfamethoxazole. The four bars for each agent correspond to the entire dataset (all, shaded green) or the three subsets (see key). The inset shows the number of strains resistant to a given number of antimicrobials. Penicillin- and/or erythromycin-resistant strains are colored with darker green (see key). FRC0402, the most multidrug-resistant isolate with resistance to 12 agents, is highlighted

expected resistance phenotypes (Additional file 4: Fig. S10), particularly for *ermX* (macrolide resistance; phi coefficient = 0.66 with erythromycin resistance), *sul1* (sulfonamide resistance; phi = 0.80), and *aph (3′)-Ia* (kanamycin resistance; phi = 0.84). In strains FRC0137 and FRC0375, this latter gene was linked to *aph (3′)-Ib* (strA), *aph (6)-Id* (strB), and *ermX* on a Tn5432-like genomic region with an IS1249 insertion sequence [65]. The phylogenetic distribution of ARGs (Fig. 5; Additional file 4: Fig. S6) revealed their presence in multiple unrelated sublineages, consistent with independent acquisitions by horizontal gene transfer. Gene *ermX* was present either in proximity to gene *pbp2m* (see below) or in a fragmented insertion-sequence rich accessory region. Gene *dfrA16* was associated with *sul1* on a reported [37] class 1 integron (see the "Discovery of a multidrug-resistant conjugative plasmid carrying the gene *pbp2m*" section). Tetracycline resistance was associated either with the ribosomal protection protein genes tet(O) or tet(W) or with the efflux pump gene tet33. These three genes were present in distinct strain subsets and appear to contribute independently to tetracycline resistance in *C. diphtheriae* (Fig. 5); they were mostly associated with insertion sequences but not with other ARGs.

Next, in order to identify novel genetic determinants potentially associated with antimicrobial resistance in *C. diphtheriae*, a GWAS approach was followed, based on either core genome SNPs or accessory gene presence/absence. SNPs that were strongly associated with ciprofloxacin, trimethoprim, and rifampicin resistance were identified within genes for gyrase subunit A, dihydrofolate reductase, and RNA polymerase subunit B, respectively (Additional file 6: Table S5; Additional file 4: Fig. S11), consistent with known mechanisms and validating our approach. SNPs were also found to be associated with penicillin, kanamycin, and tetracycline resistance (Additional file 6: Table S5), but based on the annotations of the genes where they are located, the functional implications of these SNPs are unclear in these cases. No association was found for penicillin resistance within the core PBP genes using the genome-wide approach. However, using a concatenation of the amino acid sequences of the seven identified putative PBPs of *C. diphtheriae*, we identified amino acid positions that were statistically associated with penicillin resistance (Additional file 4: Fig. S12). The identified positions were mapped onto the predicted functional domains of the different PBPs (Additional file 4: Fig. S13) revealing several mutation hotspots. A number of significant SNPs were

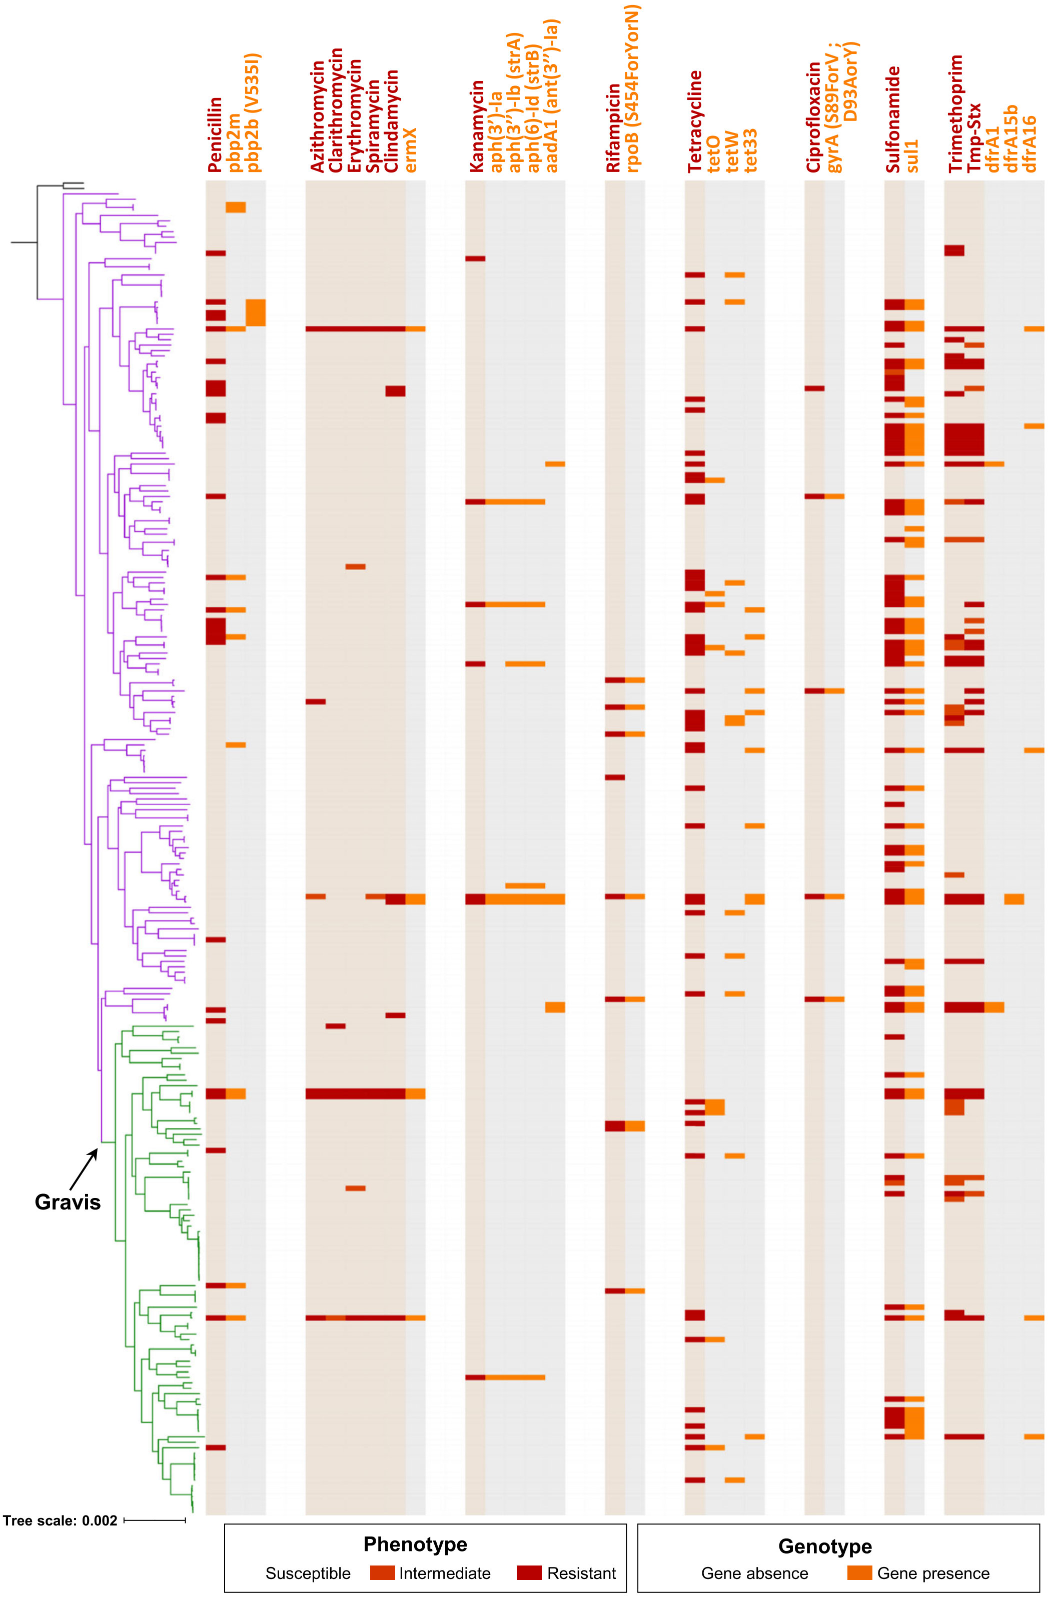

Fig. 5 (See legend on next page.)

(See figure on previous page.)
Fig. 5 Phylogenetic distribution of antimicrobial resistance phenotypes and genes. The phylogenetic tree is the same as in Fig. 1; the Mitis branch is in purple, the Gravis branch in green. To the right of the tree, each bloc indicates first the phenotype (red, resistant; see key) and relevant corresponding genotypes (orange, gene or mutation presence)

found within the transpeptidase (TP) domains of the different PBPs, but none of the mutations mapped to the conserved transpeptidation motif. Other mutations were found outside the TP domains, for instance, in the transglycosylase and PASTA domains of PBP1b or in the dimerization domain of PBP2b.

GWAS analysis of accessory genes demonstrated significant associations with phenotypic resistance. Associated genes included those mentioned above for erythromycin, tetracycline, kanamycin, sulfonamide, and trimethoprim (Additional file 6: Table S5), showing that these genes are the main mechanisms of resistance to these antimicrobial agents in *C. diphtheriae* populations. In addition, an accessory penicillin-binding protein gene (which we name *pbp2m*) was strongly associated with penicillin resistance. This gene is described in more detail below.

Discovery of a penicillin-binding protein (PBP2m) associated with penicillin resistance

The PBP gene *pbp2m* was observed in 11 isolates, 8 of which were penicillin resistant with minimum inhibitory concentrations (MIC) ranging from 0.19 to 1.5 mg/L. Two of these isolates were also resistant to amoxicillin and one was in addition resistant to oxacillin (Additional file 2: Table S2). The phylogenetic distribution of *pbp2m*-positive strains was compatible with multiple independent acquisitions of the gene through horizontal gene transfer (Fig. 5). Sequence analysis showed that the newly identified PBP2m is almost identical (3 differences out of 593 amino acids, 99.5%) to PBP2c from *C. jeikeium*, a class B PBP with an N-terminal signal peptide followed by a lipobox domain and the C-terminal transpeptidase domain (Additional file 4: Fig. S13). The *C. jeikeium* PBP2c is a low-affinity PBP and was associated with beta-lactam resistance in *C. jeikeium* [66].

To demonstrate the role of PBP2m in penicillin resistance, its gene was PCR amplified from FRC0402 and cloned into the pTGR5 plasmid (Additional file 4: Fig. S1). Transformation of the plasmid into *C. glutamicum* strain ATCC 13032 raised the MIC for penicillin from 0.125 to 1.5 mg/L, and the MICs of the other beta-lactams amoxicillin, oxacillin, and cefotaxime also increased importantly (Fig. 6; Additional file 7: Table S6). In contrast, MICs of non-beta-lactam agents were not changed. Imipenem was less effective against the transformant based on disk diffusion but not based on E-test. Transformation with the empty plasmid used as control

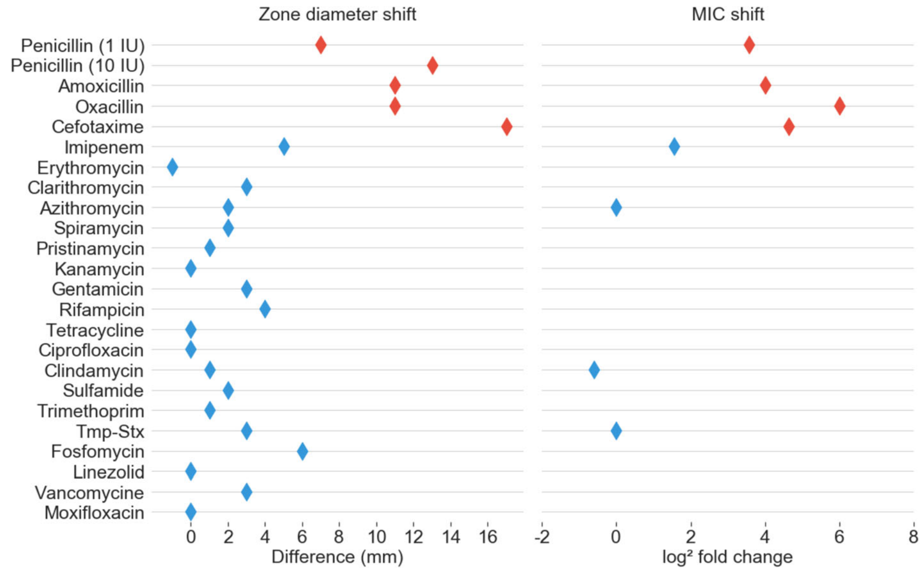

Fig. 6 Phenotypic effect of *pbp2m* expression. Compared susceptibility phenotypes for *C. glutamicum* transformants with plasmid pTGR5 containing, or not, the *pbp2m* gene. Left, the shift in zone diameter size; right, the shift in the minimum inhibitory concentration (MIC). Diamonds are positioned on the scales, at positions corresponding to the difference of zone diameters (without *pbp2m* – with *pbp2m*) or the log2 of MIC ratios (with *pbp2m*/without *pbp2m*). Red, penicillins or cephalosporins; blue, other agents. Tmp-Stx, trimethoprim-sulfamethoxazole

did not affect the MIC of any agent. These results show that PBP2m confers resistance to a broad range of beta-lactams.

Discovery of a multidrug-resistant conjugative plasmid carrying the gene *pbp2m*

Strain FRC0402, a *tox*-negative isolate from La Réunion Island, stood out as being resistant to 12 agents (Fig. 4 inset). In addition to *pbp2m*, this isolate carried genes *sul1*, *ermX*, and *dfrA16* and a *tetA* family *tet(Z)*-like (71%) tetracycline efflux gene. To define the genomic context of resistance genes, a complete genome sequence was obtained. The assembly revealed a chromosome of 2,397,465 bp and a circular plasmid of 73,763 bp (Fig. 7), which we propose to name pLRPD (for large resistance plasmid of *C. diphtheriae*).

The *pbp2m* gene was located on the large plasmid in a region comprising three other genes, a *blaB* beta-lactamase family gene, a LysR family regulator gene, and the *ermX* gene, flanked by two insertion sequences (IS*1628*) of the IS6 family (Fig. 7). With disparate direct repeat sequences, it remains unclear if this region

Fig. 7 Map of plasmid pLRPD from isolate FRC0402. Predicted coding sequences are portrayed by arrows and colored based on the predicted gene function (refer to key). Inner blue circle, G+C% content; inner green circle, A+T% content. IS3502 annotation is putative; IS3503 is truncated

represents a single transposable unit or a mosaic of gene acquisition events in pLRPD. A nearly identical PBP was observed in 78% of publicly available *C. jeikeium* genomes, in 57% of *C. striatum* genomes and in multiple other *Corynebacterium* genomes (Additional file 8: Table S7). However, the genetic context of PBP2m was highly variable in *C. diphtheriae* and among other *Corynebacterium* species (Additional file 4: Fig. S14). A putative transposable PBP-containing unit (PCU) comprising genes *pbp2m*, *blaB*, and *lysR*, commonly flanked by IS*3503* (IS*256* family) with a fragment identified in pLRPD (Fig. 7), appeared to be highly conserved and was associated variably with *ermX* in *C. diphtheriae* and with a helicase in *C. diphtheriae* and other *Corynebacterium* species. The PCU was sometimes found in 2 or 3 tandem copies and was chromosomally located in most genomes.

Further elements carried by pLRPD included an integron carrying genes *dfrA16*, *qacL*, and *sul1*, as well as elements of a putative conjugation apparatus gene cluster (Fig. 7). Our conjugation experiments aiming to demonstrate the transfer of pLRPD into recipient *C. diphtheriae* isolates failed. This plasmid was not found in other *C. diphtheriae* strains.

Discussion

Strains of *C. diphtheriae* that are resistant to antimicrobial therapy may compromise the management of diphtheria cases and the control of pathogen transmission. Here, we aimed to define the genomic determinants of resistance to penicillin and other antimicrobial agents in *C. diphtheriae* and to analyze the relationships of resistance with diphtheria toxin production, biochemical variants, and phylogenetic sublineages. To this aim, we characterized phenotypically and genotypically a large sample of *C. diphtheriae* isolates from diverse geographic and temporal origins. We confirmed that the species is made of multiple phylogenetic sublineages [9, 13, 67] and showed that homologous recombination contributes five times more to their diversification than mutation, consistent with previous evidence of recombination in *C. diphtheriae* populations [12, 13].

Historically, *C. diphtheriae* isolates have been classified into three main biovars, but the links between biovars and phylogenetic structure have remained obscure. Whereas previous work concluded on the absence of an association [11], our phylogenetic analyses reveal that Gravis and Mitis, the two main biovars of *C. diphtheriae*, are associated strongly with two phylogenetic lineages. Lineage Gravis appears to have acquired ancestrally a gene cluster comprising the extracellular glycogen debranching enzyme gene *spuA* [62]. Although the Gravis phenotype was associated with *spuA* within lineage Gravis, other genomic determinants of glycogen utilization remain to be discovered within the Mitis lineage. Whereas most of our biovar Belfanti isolates were excluded from this work because they belonged to *C. belfantii* or *C. rouxii*, a few Belfanti isolates did belong to *C. diphtheriae.* For three of them, mutations leading to a non-functional nitrate reductase were uncovered, explaining the phenotypic switch to biovar Belfanti. Our results show that biotyping is subject to parallel evolution, perhaps due to a yet-unknown selective pressure, and has limited species-level identification (as Belfanti is found in the three species *C. diphtheriae*, *C. belfantii*, and *C. rouxii*) or epidemiological typing value.

The most important factor of *C. diphtheriae* pathogenicity is the diphtheria toxin. Despite early realization that it is encoded on a prophage [5], few studies have investigated the phylogenetic distribution of the *tox* gene in *C. diphtheriae* [8, 9]. Here, we show that *tox*-positive strains mainly belong to the Mitis lineage and to early-diverging branches of the Gravis lineage. The distribution of *tox*-positive isolates into multiple Mitis sublineages is strongly indicative of independent acquisitions of the toxin gene. Alternately, this pattern might result from initial acquisition of the *tox* gene, followed by secondary loss in multiple sublineages. The phylogenetic pattern is also consistent with an ancestral presence of the *tox*-bearing phage in the Gravis lineage, with subsequent loss of the *tox* gene in the branch leading to the ancestor of most Gravis isolates. Future work should investigate the dynamics of the lysogenic corynephages and molecular determinants of their sublineage distribution. One important open question is the likelihood of *tox*-negative strains acquiring the *tox* gene during colonization, infection, or short-term epidemiological timeframes [7].

Remarkably, except for early-diverging sublineages, only one Gravis sublineage was found to carry the *tox* gene. This sublineage happens to correspond to the largest outbreak in recent times, which occurred in Newly Independent States of the ex-Soviet Union in the 1990s [13, 14, 38]. This sublineage, which comprises the ST8 reference strain NCTC13129, is genetically distant from other *tox*-positive lineages, which belong to the Mitis lineage. Hence, its antigenic structures or other pathogenicity properties may have diverged from those of more common *tox*-positive isolates, which might have contributed to its exceptional transmission in the 1990s, in addition to the decline in vaccine coverage [14]. Of note, biovar Gravis was named to reflect a perceived higher severity of infection compared to diphtheria cases caused by biovar Mitis isolates [68, 69]. Recently, it was shown that most diphtheria vaccines contain, besides the anatoxin, multiple other *C. diphtheriae* immunogens [22]. The impact of vaccination on the evolution of *C.*

diphtheriae populations, and possible variations of cross-protection as a function of strain diversity, is currently undefined. This work provides a framework onto which future studies can build to address this important question.

Although antimicrobial-resistant *C. diphtheriae* strains have been reported on numerous occasions [23, 32], knowledge on antimicrobial resistance in *C. diphtheriae* is largely fragmented and suffers from the lack of harmonization. Breakpoints used to define resistance vary according to world region and have changed over time within single countries [70]. The lack of consensus on the definition of resistance restricts our ability to define the magnitude of the problem and its global significance.

We aimed to define biologically meaningful cutoffs [64] based on susceptibility phenotype distributions, taking advantage of our large and diverse sample. Our data allowed us to propose tentative ecological cutoffs for *C. diphtheriae*. This approach should in the future be extended to MIC values [71] and should use larger and more diverse strain collections. Nevertheless, our analyses suggest that non-susceptibility to at least one antimicrobial agent was acquired by half of *C. diphtheriae* strains, regardless of lineage, biovar, or toxigenic status. This study further suggests that acquired resistance to penicillin, the first-line therapy against diphtheria, is far from being rare, affecting > 15% of *C. diphtheriae* isolates collected in the last decade in France and its overseas territories. Besides, 10.4% of these isolates were multidrug-resistant. The high prevalence of resistance to penicillin, tetracycline, and trimethoprim/sulfamethoxazole found here is consistent with susceptibility surveys of recent *C. diphtheriae* isolates in Algeria [29], Indonesia [31, 72], and India [73]. Many high-income countries such as France have chosen to use amoxicillin as the first choice for antibiotic therapy [74], as this molecule remains highly active. Still, widespread penicillin resistance is concerning, since diphtheria mainly occurs in resource-poor settings where penicillin G is largely used. In contrast, resistance to erythromycin and other macrolides remains rare. Our results call for concerted research into the magnitude of the antimicrobial resistance threat in *C. diphtheriae*.

Knowledge of the genetic mechanisms of antimicrobial resistance is critical for defining appropriate treatments, refining diagnostics, and conducting epidemiological studies of antimicrobial resistance. Resistance genes to several antimicrobial classes have been described in *C. diphtheriae* [36, 37, 75], while additional genes described in other *Corynebacterium* species [76] might also be present in *C. diphtheriae*. Here, we defined the prevalence and phylogenetic distribution of previously reported and newly identified resistance determinants in *C. diphtheriae*. We demonstrate the co-occurrence of resistance phenotypes and genes, suggesting a causative link in multiple instances. We further show that resistance genes have been acquired independently in multiple sublineages, demonstrating a dynamic resistome in *C. diphtheriae*. In addition, we demonstrate an association between alterations in chromosomally encoded targets and phenotypic resistance for quinolone, trimethoprim, and rifampicin. Fluoroquinolone resistance was previously linked to mutations in the *gyrA* gene in *C. amycolatum* [77], *C. striatum* [78], and *C. belfantii* [79] but seemingly never for *C. diphtheriae*. Finally, we demonstrate the co-occurrence within some strains of multiple resistance determinants and uncover a previously undescribed large resistance plasmid in *C. diphtheriae*. The mechanism of genetic transfer of this plasmid remains to be investigated. This work provides the first overview of the *C. diphtheriae* resistome and will facilitate further studies into the evolutionary emergence of multiresistant *C. diphtheriae* strains.

Here, we discovered an accessory PBP (PBP2m) and experimentally showed it to confer resistance to penicillin and other beta-lactam antimicrobial agents. Its distribution in multiple sublineages, and its presence in other *Corynebacterium* species, clearly demonstrates its horizontal transfer, and we revealed a multiplicity of genomic contexts in which it is found within *Corynebacterium*. PBP2m is a putative low-affinity PBP, which would explain why it is less affected by beta-lactam antibiotics. Very recently, Forde et al. [80] have reported high-level penicillin resistance (MIC > 256 g/L) in *C. diphtheriae* strain BQ11 and have attributed this phenotype to a penicillin-binding protein located on transposon Tn3503. We found that the *pbp2m*-containing unit is 99.92% similar to Tn3503, which additionally harbors a helicase (Additional file 4: Fig. S14). Besides, PBP2m is 100% identical to the PBP from BQ11 and therefore also possesses the V361A alteration (using *C. jeikeium* as reference) that was hypothesized to confer high-level penicillin resistance [80]. Further studies on the expression of *pbp2m* in its variable genetic backgrounds are required to understand the observed difference in penicillin resistance levels. The location of *pbp2m* on a mobile element and its association with beta-lactam and carbapenem resistance represents a public health threat.

The seven chromosomal PBPs of *C. diphtheriae* (including the newly annotated PBP4b) were investigated to identify amino acid sequence polymorphisms associated with penicillin resistance. Although several alterations were significantly associated, none was directly implicated with the catalytic residues of the transpeptidase or transglycosylase domains. The association with resistance may not be directly linked to these catalytic residues but could be due to secondary sites that are thought to interfere with beta-lactam ligand binding. While biochemical and structural studies are necessary to understand how these mutations affect penicillin susceptibility, we postulate that some changes in these domains could lead to allosteric effects ultimately resulting in beta-lactam resistance, as described for *Staphylococcus aureus* PBP2a [81, 82] or *Streptococcus pneumoniae* PBP2x [83]. Other SNPs might simply have been hitchhiking due to their physical linkage with functionally important SNPs [84].

Conclusions

Our phylogenetic analyses showed that *C. diphtheriae* is highly diverse and comprises multiple sublineages that are grouped into two major lineages, characterized by distinctive associations with biovars Mitis and Gravis and with the diphtheria toxin gene. Antimicrobial resistance remains rare in France and its overseas territories, but multidrug-resistant strains were found and have a wide phylogenetic distribution. Analyses of the genetic bases of antimicrobial resistance defined the contribution of previously described mechanisms of resistance and uncovered a penicillin-binding protein, PBP2m, associated at the population level with penicillin resistance and shown experimentally to confer resistance to several beta-lactam antimicrobial agents. PBP2m is encoded in diverse genetic contexts, including on a large putatively conjugative resistance plasmid. This study reveals how biovars, diphtheria toxin gene, and antimicrobial resistance are associated with the phylogenetic diversity of *C. diphtheriae* strains, and provides novel data into the evolutionary dynamics of these medically important features. This framework will facilitate future studies investigating the emergence of sublineages of *C. diphtheriae* involved in diphtheria outbreaks, antimicrobial resistant infections, and the patterns and drivers of global spread of *C. diphtheriae* sublineages.

Acknowledgements

We thank Vincent Enouf and the P2M core facility of Institut Pasteur for genomic sequencing. We are indebted to Collection de l'Institut Pasteur for providing reference strains of ribotypes, which were deposited following their described by Grimont and colleagues in 2004 [40]. We thank Valerie Bouchez for help with the Oxford Nanopore Technologies sequencing.

Authors' contributions

S.B. conceived, designed, and coordinated the study. A.C-L., E.B., M.B., and M.D. performed the microbiological cultures of the isolates and their biochemical and molecular characterizations. M.H., L.G.P., C.R., S.L.B., M.B.-P., M.D., and S.B. analyzed the genomic and phenotypic data. J.T. reviewed the clinical source data of the isolates. Q.G. and A.-M.W. performed the pbp2m cloning experiments and analyzed the PBP sequences. X.D. provided help with the phylogenetic, recombination, and GWAS analyses. S.B. wrote the initial version of the manuscript. All authors provided input to the manuscript. All authors read and approved the final manuscript.

Funding

MH was supported financially by a PhD grant from the European Joint Programme One Health, which has received funding from the European Union's Horizon 2020 Research and Innovation Programme under Grant Agreement No. 773830. LGP was supported financially by a grant from the Institut Français de Bioinformatique, the national infrastructure for services in bioinformatics created in the frame of the French Government's Investissement d'Avenir program. QG was funded by MTCI PhD school (ED 563). CR was supported by a Pasteur-Roux fellowship from Institut Pasteur. SLB received support from a Victorian Fellowship, provided by VESKI and funded by the State Government of Victoria, Australia.
The National Reference Center for Corynebacteria of the *Diphtheriae* complex receives support from Institut Pasteur and Public Health France (Santé Publique France, Saint Maurice, France). This work was supported financially by the French government's Investissement d'Avenir program Laboratoire d'Excellence "Integrative Biology of Emerging Infectious Diseases" (ANR-10-LABX-62-IBEID). AW and QG receive support from Institut Pasteur and the CNRS (France).

Availability of data and materials

The genomic sequencing data generated in this study were deposited in the European Nucleotide Archive (ENA) database and are accessible through the BioProject PRJEB22103 (https://www.ebi.ac.uk/ena/browser/view/PRJEB22103) [85].

Ethics approval and consent to participate

To conduct the research, we used bacterial strains, which are not considered human samples. Accordingly, this research was not considered human research and is out of the scope of the decree n° 2016-1537 of November 16, 2016, implementing law n° 2012-300 of March 5, 2012, on research involving human subjects. Therefore, no ethics approval was needed and no informed consent was required.
All French bacteriological samples were collected in the frame of the French national diphtheria surveillance and are collected, coded, shipped, managed, and analyzed according to the French National Reference Center protocols that received approval from the French competent body CNIL (Commission Nationale Informatique et Libertés; approval number: 1474671). Other strains were obtained from culture collections.
The research conformed to the principles of the Helsinki Declaration.

Pharmacogenomics of NSAID-Induced Upper Gastrointestinal Toxicity

L. McEvoy, D. F. Carr* and M. Pirmohamed

Department of Pharmacology and Therapeutics, University of Liverpool, Liverpool, United Kingdom

Non-steroidal anti-inflammatory drugs (NSAIDs) are a group of drugs which are widely used globally for the treatment of pain and inflammation, and in the case of aspirin, for secondary prevention of cardiovascular disease. Chronic non-steroidal anti-inflammatory drug use is associated with potentially serious upper gastrointestinal adverse drug reactions (ADRs) including peptic ulcer disease and gastrointestinal bleeding. A few clinical and genetic predisposing factors have been identified; however, genetic data are contradictory. Further research is needed to identify clinically relevant genetic and non-genetic markers predisposing to NSAID-induced peptic ulceration.

Keywords: pharmacogenomic, NSAID (non-steroidal anti-inflammatory drug), gastrointestinal toxicities, aspirin, adverse drug reaction

INTRODUCTION

NSAIDs comprise a heterogeneous group of non-opioid drugs with effective analgesic, anti-inflammatory and antipyretic properties (Calatayud and Esplugues, 2016). They are employed in the treatment of acute and chronic pain conditions characterized by inflammation. While aspirin was used as an analgesic in the past, its main use nowadays is as an antithrombotic particularly at low doses, and for cancer prevention (Shaheen et al., 2002; Sandler et al., 2003; Bashir et al., 2019). Overall, NSAIDs are well tolerated, especially when used short-term (Ong et al., 2007), but because of the enormous usage globally, they are often implicated in adverse drug reactions.

NSAIDs, including low dose aspirin (LDA), are one of the most commonly prescribed classes of medication, accounting for approximately 5–10% of prescriptions globally (Onder et al., 2004). Two decades ago, >30 million people were estimated to take NSAIDs daily (Singh and Triadafilopoulos, 1999). Pharmacoepidemiological studies indicate that NSAID use is increasing. A 2010 National Health Interview Survey (CDC, United States) reported increases of 57 and 41% in aspirin and NSAID use, respectively, over 5 years (Zhou et al., 2014), but this may still be an underestimate given the wide availability of aspirin and ibuprofen as over-the-counter (OTC) formulations. Telephone surveys of United States OTC NSAID users found that drugs were often used/taken inappropriately with 26% of respondents exceeding recommended doses (Goldstein and Lefkowith, 1998; Wilcox

et al., 2005; Goldstein and Cryer, 2015). In Germany, analgesic use significantly increased from 19.2% in 1998 to 21.4% in 2008–2011. This rise was found to be attributed exclusively to the use of OTC formulations increasing from 10.0 to 12.2% (prescribed analgesic use remained constant at 7.9%). Ibuprofen was most commonly used, followed by aspirin (Sarganas and et al., 2015). Higher frequencies of ibuprofen use have also been documented in Denmark (Olsen and et al., 2011) and Spain (Gómez-Acebo and et al., 2018). In contrast, however, diclofenac was reported as the most frequently used NSAID (followed by ibuprofen) in a study across 15 countries (Australia, Bangladesh, Canada, China, China (Hong Kong), England, Indonesia, Malaysia, New Zealand, Pakistan, Philippines, Singapore, Taiwan, Thailand, and Vietnam) (McGettigan and Henry, 2013). The trend for increasing OTC analgesic use has also been echoed in Australia. Between 2001 and 2009, there was a 15% increase in the use of ibuprofen, naproxen and diclofenac (Stosic et al., 2011). In general practice, NSAID use by the elderly is prolific, reported at 96% (96% in males, 96.7% in females) in patients >65 years (Pilotto et al., 2003).

NSAIDs are responsible for ~30% of ADR hospitalisations (Pirmohamed et al., 2004); cardiovascular, gastrointestinal (GI) and renal complications are associated with their use (Bhala et al., 2013; Szeto et al., 2020). Estimates suggest that 5,000–16,500 deaths in the United States and 400–1,000 deaths in the United Kingdom are a direct consequence of NSAID-induced upper GI ulceration and bleeding annually (Wolfe et al., 1999; Langman, 2001; Hawkey and Langman, 2003).

Genetic factors predisposing to NSAID-induced upper GI toxicity have been described, yet findings have been inconsistent and contradictory. This mini review discusses current literature and seeks to identify areas to focus collaborative efforts in the field.

NSAID-INDUCED UPPER GASTROINTESTINAL TOXICITY

The first serious NSAID-induced adverse event to be identified was upper GI injury (Walt et al., 1986; Langman, 1988). It is also recognized as one of the most predominant ADRs in the United States (Butt et al., 1988; Fries, 1996). NSAIDs and aspirin have now overtaken *Helicobacter pylori* as the principal cause of GI toxicity in western countries (Musumba et al., 2009; Bjarnason, 2013). "Gastrointestinal toxicity" refers to a collection of heterogeneous pathologies affecting various tissues and organs of the GI tract.

Clinical Problem and Disease Burden

NSAID-related ADRs range from mild to severe and can result in death. Cryer (2004) conveniently stratified typical manifestations of NSAID-induced GI injury in to three tiers: dyspepsia; asymptomatic ulceration; and more serious complications (GI bleeding, perforation, obstruction, symptomatic ulceration) (Cryer, 2004). Although upper GI events are more common, the entirety of the GI tract may be affected (Maiden et al., 2005). Lower GI complications are not as well defined (Langman et al., 1985). In the large intestine, non-specific colitis, increased gut permeability, malabsorption and bleeding have been reported. Inflammatory bowel disease (IBD) (Bjorkman, 1998; Faucheron, 1999; Forrest et al., 1999) and diverticular disease (Campbell and Steele, 1991) may also be exacerbated by NSAIDs. In this article, we only focus on upper GI events.

Patient characteristics increasing the risk of NSAID-induced GI events have been identified (summarized in **Table 1**). These include: advanced age (Fries et al., 1991; Hernández-Díaz and Rodríguez, 2000; Russell, 2001; Sostres et al., 2013; Chi et al., 2018); *H. pylori* infection (Leontiadis and et al., 2007; Sostres et al., 2010); multimorbidity/comorbidity (Chi et al., 2018; Jankovic et al., 2009; Weil and et al., 2000; Kim, 2015); polypharmacy (Davies and Wallace, 1996) and concomitant medications (de Abajo et al., 1999; Silverstein et al., 2000; Sorensen et al., 2000; Garcia Rodriguez and Hernández-Díaz, 2001; Johnsen et al., 2001; Lazzaroni and Bianchi Porro, 2001; Laine et al., 2002; de Jong et al., 2003; Helin-Salmivaara et al., 2007; Lanas et al., 2007; Åhsberg et al., 2010; Masclee et al., 2013; Sostres et al., 2013; Anglin et al., 2014; Olsen et al., 2020). Studies have shown that the risk of NSAID-induced GI complications is dose-dependent (Silverstein and et al., 1995; Bombardier et al., 2000; Laporte et al., 2004; González-Pérez and et al., 2014; Figueiras and et al., 2016) and remains linear over time (Silverstein and et al., 1995; Bombardier et al., 2000; Rostom et al., 2007; Goldstein et al., 2011).

Increased/prolonged exposure (habitual in chronic pain conditions through high-dose and multiple-NSAID use) elevates the risk and/or severity of toxicity (Garcia Rodriguez and Hernández-Díaz, 2001; Bhala et al., 2013; Lanas et al., 2015). Treatment guidelines recommend the lowest effective dose for the shortest period of time. Whilst it is recommended that long-term NSAID use should be avoided (Bhatt et al., 2008; Lanza et al., 2009), this is difficult in practice for many patients. Individuals with a past history of GI injury (including uncomplicated or complicated ulcers) are considered at the highest risk of complications (Sostres et al., 2013; Chi et al., 2018; Silverstein and et al., 1995; Van Hecken et al., 2000; Laine, 2001; Laine, 2006). COX-2 inhibitors (Coxibs) and gastroprotective therapies such as proton pump inhibitors (effective anti-secretory agents) help to mitigate the risk of GI injury (Gargallo et al., 2014; Melcarne et al., 2016).

Mild upper GI symptoms are reported by up to 40% of NSAID users (Larkai et al., 1989; Hirschowitz, 1994). The most clinically significant upper GI NSAID-induced ADRs are symptomatic and/or complicated peptic ulcer. Symptomatic peptic ulcer incidence rates in chronic NSAID users are between 2–4% annually (1–3% for serious ulcer/upper GI complications) (Cryer, 2004; Silverstein et al., 2000; Silverstein and et al., 1995; Bombardier et al., 2000; Blower and et al., 1997; Paulus, 1988), a threefold to fivefold increase compared to non-users (García Rodríguez and Jick, 1994; Gutthann et al., 1997; Hernández-Díaz and Rodríguez, 2000; Cryer, 2004; Gevers et al., 2014).

It is important to note that symptoms do not necessarily correlate with the severity of peptic ulcer disease and/or its complications (Sostres et al., 2013)—50–60% of patients can

TABLE 1 | Reported risk factors for developing NSAID-induced upper GI toxicity.

Patient characteristic	Description	References
Patient factors		
Advanced age	>60 years	Fries. (1996), Hernández-Díaz and Rodríguez, (2000), Chi et al. (2018)

be asymptomatic (including having unremarkable endoscopies (McCarthy, 1989)) prior to developing potentially fatal NSAID-induced complicated ulcers (Armstrong and Blower, 1987). A prospective observational study found this figure to be as high as 80% (Singh and et al., 1996). In NSAID users who do develop lesions (endoscopically confirmed subepithelial hemorrhages, erosions, and ulcers), healing often occurs before symptoms manifest—"silent ulceration"—because of efficient gastroprotective mechanisms (Larkai et al., 1987; Lanas and Hunt, 2006; Sostres et al., 2013; Carr et al., 2017). Notwithstanding, peptic ulcer prevalence ranges from 15–40% in chronic NSAID users (McCarthy, 1989; Geis et al., 1991; Dajani and Agrawal, 1995; McCarthy, 1998). Gastric ulcer risk is slightly higher than duodenal ulcer risk (McCarthy, 1989; Larkai et al., 1987; McCarthy, 1998; Henry et al., 1993; Gabriel et al., 1991; Griffin and et al., 1991). Endoscopy remains the gold standard for PUD diagnosis (Dunlap and Patterson, 2019).

LDA is extensively used as prophylactic therapy against cardiovascular thrombotic events in high-risk individuals (Collaboration., 2002; Patrono et al., 2004). Throughout Europe and the United States, approximately 23% of the population use aspirin at least once per week (Larson et al., 2005). A prospective analysis of ADRs requiring hospitalization found that aspirin was the most commonly implicated, responsible for 18% of admissions; 74% of these patients were taking LDA. GI bleeding was the most common adverse event, observed in 72% of aspirin-related admissions (Pirmohamed et al., 2004). This is most likely to be due to aspirin-associated peptic ulceration (Niv et al., 2005). Generally, individuals on LDA therapy are older and multimorbid, increasing the likelihood of polypharmacy; some patients take both aspirin and NSAID(s) (Murray and et al., 1998) which is known to further raise the risk of GI toxicity and bleeding (Silverstein et al., 2000; Sorensen et al., 2000; Garcia Rodriguez and Hernández-Díaz, 2001). GI symptoms in chronic LDA therapy are challenging and are a reason for discontinuation of treatment and non/poor compliance (Cayla et al., 2012). Adverse events have been cited as responsible for LDA-discontinuation in almost 50% of patients (Herlitz et al., 2010). Discontinuation is associated with increased risk of new CV events (Biondi-Zoccai et al., 2006; Sostres and Lanas, 2011) and should only be advocated after sound clinical assessment when the risk of GI bleeding outweighs that of CV events.

NSAIDs differ in their propensity to cause upper GI injury based on their COX-1/COX-2 selectivity. Due to selective COX-2 inhibition, coxibs offer greater GI safety and are associated with a lower risk of upper GI injury and clinically significant ulcer complications compared to traditional NSAIDs (tNSAIDs) (Rostom et al., 2007; Chan et al., 2010). A meta-analysis by Castellsague et al. (2012) calculated the relative risk (RR) of upper GI complications as follows:

- RR <2 aceclofenac, celecoxib, ibuprofen.
- RR 2 to <4 diclofenac, ketoprofen, meloxicam, nimesulide, rofecoxib, sulindac.
- RR 4—5 diflunisal, indomethacin, naproxen, tenoxicam.
- RR >5 azapropazone, ketorolac, piroxicam (Castellsague et al., 2012).

Celecoxib has been shown to be associated with a lower risk of upper-GI events (Silverstein et al., 2000; García-Rayado et al., 2018) whilst celecoxib plus proton pump inhibitor is preferred over tNSAID (naproxen) plus proton pump inhibitor to reduce the risk of recurrent upper GI bleeding in individuals requiring concomitant aspirin and NSAID (Chan et al., 2017).

Mechanisms of NSAID-Induced Gastrointestinal Toxicity

NSAID pharmacology, first described by Vane. (1971), is well documented (Vane, 1971). The cyclo-oxygenase (COX) pathway is responsible for the biosynthesis of prostanoids, including prostaglandins (PGs) and thromboxane (TX), from arachidonic acid (AA). Two clinically significant COX isoenzymes exist, COX-1 and COX-2, encoded by the genes *PTGS1* and *PTGS2,* respectively (Plaza-Serón et al., 2018). Prostanoids are pro-inflammatory mediators: PGs produced by COX-1 (and to a lesser degree, COX-2 (Wallace, 2008)) are essential in maintaining/regulating gastroprotection (Dickman and Ellershaw, 2004). Fundamentally, PG generation is forestalled by NSAIDs via reversible inhibition (except aspirin, an irreversible inhibitor (Funk et al., 1991; Catella-Lawson et al., 2001)) of COX isoenzymes, thereby decreasing inflammation.

NSAIDs are sub-divided based on COX-selectivity: tNSAIDs are non-selective, inhibiting both isoenzymes. COX-2 selective inhibitors (coxibs) are isoform-specific, designed to help mitigate the GI adverse events of tNSAIDs whilst retaining anti-inflammatory and analgesic activity. Inhibition of COX-2 is the desired therapeutic aim of NSAIDs. Upper GI toxicity is more common with tNSAIDs than with coxibs (Pilotto et al., 2005).

Under normal conditions, gut homeostasis is maintained. However, imbalance(s) in the gastroduodenal mucosal lining may result in GI injury. Protective factors comprise the gastric epithelial cells and hydrophobic mucus-bicarbonate bilayer, cellular repair, remodeling, restitution, and adequate blood supply–all of these are PG-regulated. Microvascular damage reduces gastric mucosal blood flow, an initial and crucial event in ulcer pathogenesis (Musumba et al., 2009; Bjarnason et al., 2018). The locale of greatest localized ischemia correlates with the site of most NSAID-induced ulceration, the gastric antrum (Musumba et al., 2009). Gastroprotective strategies can mitigate the risk of PUD, but will not be discussed further in this review: Wallace. (2008), Musumba et al. (2009), Bjarnason et al. (2018) provide excellent analyses (Wallace, 2008; Musumba et al., 2009; Bjarnason et al., 2018).

The pathogenesis of NSAID-induced GI injury is complex and multifactorial and can be divided into two broad areas: 1) Topical mechanisms (direct damage to GI mucosa). 2) Systemic mechanisms (COX-inhibition mediated).

1) *Topical effects*—NSAIDs can cause disturbances in the gastric mucosal epithelium initially through the development of erosions. NSAID toxicity is dependent on their physiochemical properties as lipid-soluble weak organic acids (pKa 3–5) (Brune et al., 1976; Brune and Graf, 1978; Rainsford and Whitehouse, 1980; Musumba et al., 2009; Bjarnason et al., 2018). Detergent properties allow interaction with surface membrane phospholipids, disrupting the mucosal barrier and provoking superficial injury (Lichtenberger, 2001). This permits NSAID to move from the lumen (low gastric pH measuring 1.5–3.5) into epithelial cells (pH neutral, 6.5–7.0), kickstarting disruption of the cellular metabolic pathways culminating in dysfunction, cytotoxic events and apoptotic pathway activation (Musumba et al., 2009; Handa et al., 2014).
2) *Systemic effects*—Robust gastric mucosal defence/repair is heavily dependent upon perpetual synthesis of COX-derived prostanoids. COX-1 is expressed in most tissues performing "housekeeping duties," maintaining and regulating various physiological functions. In the GI tract, COX-1 is abundant, producing PGs and TXs involved in cytoprotection. COX-2 is expressed at low levels in the intact stomach, but rapidly induced by COX-1 inhibition or inflammatory stimuli/injury, and produced in vast quantities by cytokines and hormones (Rainsford, 2007; Ricciotti and FitzGerald, 2011; Wongrakpanich et al., 2018).

Classically, GI complications were primarily attributed to COX inhibition: decreased PG levels resulting in increased gastric acid secretion, suppressed mucus and bicarbonate secretion, decreased mucosal blood flow and decreased cell proliferation (Cohen, 1987; Wallace, 1992; Wallace, 2008) resulting in compromised mucosal defense and delayed healing. Selective COX-1 inhibition leads to suppression of mucosal PG production by 95–98% without observable inflammation or ulceration (Ligumsky et al., 1983; Ligumsky et al., 1990; Langenbach et al., 1995; Sigthorsson et al., 2002). Inhibition of COX-2 has yielded similar results (Morham et al., 1995; Sigthorsson et al., 2002). However dual inhibition of both isoenzymes by NSAIDs induces severe gastric lesions (Wallace et al., 2000; Gretzer et al., 2001; Tanaka and et al., 2001). Both COX isoenzymes are also important in ulcer healing (Tanaka et al., 2002; Schmassmann et al., 2006; To et al., 2001; Bhandari et al., 2005; Starodub et al., 2008; Chan and et al., 2005).

In isolation, topical mechanisms are unlikely to induce notable GI toxicity. In combination with systemic factors, however, NSAIDs provoke an imbalance that incites mucosal injury. Cellular damage translates into tissue damage. COX-1 inhibition dramatically suppresses gastroprotection leading to microvascular damage, ischemia, and decreased mucus production. A complex interplay between factors ignites a cascade, involving many mechanisms that disrupt gastroprotection, engendering ulcerogenic conditions.

GENETIC RISK FACTORS

It is well acknowledged that interindividual variability exists in response to drugs, including NSAIDs, which may at least be genetic in origin. Using conventional dosing regimens in analgesia, for example, some individuals will have inadequate pain control while others will encounter toxicity from the same dose (Kapur et al., 2014). Genetic variants affecting treatment outcomes can be categorized into two broad types: 1) genes affecting drug pharmacokinetics (PK), and 2) genes affecting drug pharmacodynamics (PD) (Stamer et al., 2010; Kapur et al., 2014). It should however be noted that given the different mechanisms of action and metabolic pathways, the PK and PD genetic variability cannot be generalized across all NSAID classes. **Table 2** summarizes notable genetic risk factors for NSAID-induced upper GI toxicity.

Pharmacokinetic-Related Associations

Cytochrome P450 (CYP) gene polymorphisms are strongly associated with adverse drug reactions in general (Johansson

TABLE 2 | Notable genetic associations in NSAID-induced upper GI toxicity.

Genetic loci	Therapy	Phenotype	Association	_p_-value	Or (95%CI)	References
CYP2C9	NSAIDs—various	Endoscopically confirmed UGIB	_CYP2C9*2_ genotype (in heterozygosity or homozygosity) increases risk of GI bleeding	_p_ = 0.009	Crude OR = 1.92 (95% CI = 1.14–3.25)	Martínez et al. (2004)
CYP2C9	CYP2C9-metabolised NSAIDs	Endoscopically confirmed UGIB	Using _CYP2C9*1/*1_ wild type as control, significantly higher frequencies of bleeding observed in			Pilotto et al. (2007)
			CYP2C9*1/*3	_p_ = < 0.001	OR = 12.9 (95% CI = 2.917–57.922)	
			CYP2C9*1/*2	_p_ = 0.036	OR = 3.8 (95% CI = 1.090–13.190)	
			CYP2C9*3 allele carriers have significant risk of bleeding		Adjusted OR = 7.3 (95% CI = 2.058–26.004)	
CYP2C9	Non-aspirin NSAIDs	Endoscopically confirmed ulcers/bleeding erosions	_CYP2C9*3_ loss-of-function allele associated with acute UGIB in NSAIDs other than aspirin	_p_ = 0.0002	OR = 7.2 (95% CI = 2.6–20.3)	Carbonell et al. (2010)
CYP2C9	CYP2C9-metabolised NSAIDs	Endoscopically confirmed erosions/lesions/UGIB	_CYP2C9*3_ variant increases risk of UGIB for defined daily doses >0.5		_CYP2C9*3_ OR = 18.07 (95% CI = 6.34–51.53) Adjusted OR	Figueiras et al. (2016)
CYP2C8 and _CYP2C9_	CYP2C8/2C9-metabolised NSAIDs	Endoscopically confirmed UGIB	_CYP2C8*3_ and _CYP2C9*2_ exist in LD			Blanco et al. (2008)
			Combined _CYP2C8*3_ + _CYP2C9*2_ genotype associated with increased risk of bleeding	_p_ = 0.003	OR = 3.73 (95% CI = 1.57–8.88)	
CYP2C19	NSAIDs—various	Endoscopically confirmed UGIB	_CYP2C19*17_ associated with PUD, but not UGIB PUD distribution varied according to _CYP2C19*17_ genotype _*1/*1_, 64.3%; _*1/*17_, 71.7%; _*17/*17_, 73.8%	_p_ = 0.024	OR (additive model) = 1.47 (95% CI = 1.12–1.92)	Musumba et al. (2013)
COX-1	Aspirin and ethanol pre-treatment		SNPs _A-842G_ and _C50T_ in complete LD			Halushka et al. (2003)
			Heterozygous _A-842G/C50T_ haplotype shows significantly greater PG H (2) inhibition	_p_ = 0.01		
COX-1	Not stated	Endoscopically confirmed bleeding GU or DU	_A-842/C50T_ polymorphism has lower (yet non-significant) Risk of PU bleeding compared to wild type		OR = 0.5 (95% CI = 0.18–1.34) Adjusted* OR = 0.75 (95% CI = 0.19–3.01) Adjusted for: sex, age, smoking, NSAID/aspirin use, _H. pylori_ infection	van Oijen et al. (2006)
COX-2	Aspirin (ASA)	Surgical or endoscopic UGIB diagnosis	rs689466 T > C increases risk magnitude of UGIB in ASA users			Mallah et al. (2020)
			Variant carriers taking ASA v wild-type carriers NOT taking ASA	_p_ = 0.0022	OR = 8.22 (95% CI = 2.14–31.59)	
			Variant carriers taking ASA v wild-type carriers taking ASA	_p_ = 0.3036	OR = 2.98 (95% CI = 0.37–23.96) OR adjusted as per Mallah et al. (2020)

and Ingelman-Sundberg, 2011; Sim et al., 2013). Collectively, CYP isoenzymes mediate ~80% of phase I metabolism of clinically relevant drugs (Evans and Relling, 1999; Eichelbaum et al., 2006; Petrović et al., 2020), including NSAIDs (Blanco et al., 2005). Phase I oxidative metabolism precedes phase II conjugative metabolism (glucuronidation) driven by uridine 5′-diphosphate glucuronosyltransferases (UDP-glucuronosyltransferase, UGTs) (Kuehl et al., 2005; Monrad et al., 2014; Sandson, 2015), supplemented by sulfate conjugation (sulfotransferases) (Ulrich et al., 2006; Loetsch and Oertel, 2013). NSAID metabolism varies and this can be due to CYP polymorphisms, which have been implicated in NSAID-induced ADRs including PUD and UGIB. Studies have also demonstrated that GI damage is dose-dependent (Laporte et al., 2004; Figueiras and et al., 2016).

NSAID metabolism is specifically associated with the CYP2C subfamily (Ingelman-Sundberg et al., 2007; Musumba et al., 2013) (including the highly polymorphic CYP2C8, CYP2C9, and CYP2C19 isoforms), which make up 20% of hepatic CYP450 content and metabolize 25–30% of clinically used drugs. Polymorphisms in these genes may result in modified expression or functionality, correlating with altered metabolism and clearance which may affect bioavailability (Dai et al., 2001; Kirchheiner et al., 2002; Musumba et al., 2013; Krasniqi et al., 2016; Guengerich, 2020). Celecoxib, ibuprofen, lornoxicam and piroxicam are extensively (>90%) metabolized by CYP2C enzymes (Agúndez et al., 2009).

Estimates suggest that CYP2C9 is responsible for biotransformation and metabolic clearance in 15–20% of all phase I metabolized drugs (Goldstein and de Morais, 1994; Schwarz, 2003; Van Booven et al., 2010; Niinuma et al., 2014). CYP2C9 is involved as the main or secondary enzyme in the metabolism of most NSAIDs, including aceclofenac, aspirin, celecoxib, diclofenac, flurbiprofen, indomethacin, lornoxicam, meloxicam, naproxen, piroxicam, and tenoxicam (Davies et al., 2000; Rodrigues, 2005; Agúndez et al., 2009; Samer et al., 2013; Theken et al., 2020). With celecoxib, lornoxicam and piroxicam, CYP2C9 is the predominant enzyme, responsible for 90% of drug metabolism (Agúndez et al., 2009).

At least 62 variant alleles and multiple sub-alleles have been reported for *CYP2C9* (PharmVar (https://www.pharmvar.org/gene/CYP2C9) (PharmVar, 2017; Gaedigk et al., 2018; Theken et al., 2020) which vary in frequency ethnically, geographically and racially (Theken et al., 2020; Theken et al., 2020; Gene-specific Information Tables for CYP2C9, 2020). The allelic variants *CYP2C9*2* (rs1799853) and *CYP2C9*3* (rs1057910) show high allele frequencies in human populations (García-Martín et al., 2006); the estimated prevalence in European populations is 14% for *CYP2C9*2* and 8% for *CYP2C9*3* (Lee et al., 2002; Xie et al., 2002; Sánchez-Diz et al., 2009). These variants, most notably *CYP2C9*3*, have been extensively studied and have been associated with decreased NSAID metabolism (Visser et al., 2005; García-Martín et al., 2006; Agúndez et al., 2009; Wadelius et al., 2009; Wang et al., 2011).

Carriers of low activity *CYP2C9* alleles could be at greater risk of GI toxicity due to increased NSAID exposure. Frustratingly, case-control studies investigating associations between *CYP2C9*2* and **3* variants and NSAID-induced ADRs have often been contradictory. Several studies have reported no associations between *CYP2C9* variants and NSAID-induced PUD and/or UGIB (Martin et al., 2001; Van Oijen et al., 2005; Vonkeman et al., 2006; Lopezrodriguez et al., 2008; Ma et al., 2008; Musumba et al., 2013; Ishihara et al., 2014), while others have reported that *CYP2C9* variants predispose to PUD (Martínez et al., 2004; Pilotto et al., 2007), including the presence of a gene-dose effect (Figueiras and et al., 2016), and that there may be a combined effect of *CYP2C8*/*CYP2C9* variation (Blanco et al., 2005; Blanco et al., 2008).

Efforts to provide PGx-based guidance on NSAIDs recently culminated in the Clinical Pharmacogenetics Implementation Consortium (CPIC) guideline for *CYP2C9* and NSAIDs (Theken et al., 2020). The guideline categorizes *CYP2C9* alleles as follows: Normal function (wild type) *CYP2C9*1*, decreased function *CYP2C9*2*, **5*, **8*, **11*, and no function *CYP2C9*3*, **6*, **13* (Theken et al., 2020; Theken et al., 2020; Gene-specific Information Tables for CYP2C9, 2020). *In vitro* and clinical studies have suggested that the "decreased-function" and "no-function" *CYP2C9* alleles are substrate-dependent. A meta-analysis of *CYPC9* variant alleles on NSAID exposure, based on predicted metaboliser phenotypes (poor metabolisers, intermediate metabolisers and normal metabolisers), showed that CYP2C9 poor metabolisers had decreased metabolic clearance, a prolonged plasma elimination half-life and increased plasma concentrations. Since NSAID-induced GI toxicity is known to be dose-dependent, the risk and severity of toxicity is likely to be increased (Bhala et al., 2013; Laporte et al., 2004; Figueiras and et al., 2016; Lanas et al., 2015). Hence, to mitigate the risk of PUD, dose-reduction, careful monitoring for toxicity/ADRs and alternative therapies, (e.g. non-CYP2C9-metabolized NSAIDs (such as naproxen)) should be used (Theken et al., 2020).

A subsequent systematic review and meta-analysis by Macías et al. (2020) also addressed discrepancies in previous studies. In an exhaustive study, they concluded: "There is a clear and consistent association of the development of GI adverse events with the *CYP2C9* genotype, and the association is slightly stronger in patients with GI bleeding." Consistent with this, Theken et al. (2020), found that the associations were stronger in poor metabolisers (again based on metaboliser phenotypes) with a significant gene-dose effect. Furthermore, allele-specific analyses showed that *CYP2C9*2* was a poor risk predictor (marginal effects) in contrast to *CYP2C9*3*, which clearly showed a highly significant association with increased risk of upper GI adverse events and GI bleeding (Macías et al., 2020). This supports the findings of Figueiras and et al. (2016) who demonstrated dose-dependency in NSAID-induced GI damage and the indication that the *CYP2C9*3* allele can be used as a predictive UGIB risk marker for CYP2C9-metabolised NSAIDS (Figueiras and et al., 2016).

CYP2C8 plays an accessory metabolic role for certain NSAIDs including ibuprofen and diclofenac (Agúndez et al., 2009; Garciamartin and et al., 2004). *CYP2C9*2* is in strong linkage disequilibrium (LD) with *CYP2C8*3* (Speed et al., 2009). Findings however have again been conflicting: no association between *CYP2C8*3* and UGIB was reported by Musumba *et al.* (Musumba et al., 2013) while others have reported a positive association with GI bleeding (Agúndez et al., 2009), including when combined with *CYP2C9*2* (Blanco et al., 2005; Blanco et al., 2008).

CYP2C19 plays a minor role in NSAID metabolism. Interestingly, we showed that the *CYP2C19*17* "gain of function" polymorphism was associated with PUD (Musumba et al., 2013), irrespective of the etiology of PUD. This may be related to the fact that CYP2C19 is involved in the metabolism of AA, and more extensive metabolism of AA may impair gastric mucosal defences. This is consistent with the fact that disrupted AA metabolism is involved in PUD pathogenesis (Musumba et al., 2009).

Thus, the role of the of the *CYP2C* gene locus in predisposing to PUD is complex and likely to vary with the NSAID given, its dose and the complement of SNPs the patient has at the *CYP2C* gene locus, including at *CYP2C9* (where low activity variants will increase exposure to NSAIDs) and the gain of function polymorphism at *CYP2C19* which increases the metabolism of gastro-protective AA.

Pharmacodynamic-Related Associations

COX enzymes produce PGs from AA, playing vital roles in gastric defence. COX enzymes are the primary target of NSAIDs. There is potential for peptic ulcer pathogenesis to be influenced by functional polymorphisms in the COX-encoding genes (Agúndez et al., 2015). Individuals carrying reduced function COX-enzymes may be potentially susceptible to NSAID-induced peptic ulceration (Musumba et al., 2009).

COX-2 single nucleotide polymorphism (SNPs) have been observed to affect responsiveness to celecoxib (Lee et al., 2017), but no association with NSAID-induced GI injury was reported. Studies of *COX-1* genetic polymorphisms and GI injury have also yielded contradictory findings (van Oijen et al., 2006; Arisawa et al., 2007). As such, there is insufficient evidence currently to determine whether the *COX* gene polymorphisms predispose to NSAID-induced PUD.

A recent preliminary study by Mallah et al. identified polymorphisms in platelet activity, angiogenesis and inflammatory response genes were associated with aspirin-related UGIB (Mallah and et al., 2020), building on the findings of previous investigations (Shiotani et al., 2010; Shiotani and et al., 2013; Shiotani et al., 2014; Wu et al., 2016; Cho and et al., 2016; Milanowski et al., 2017). The group identified “positive markers,” that indicated an increased risk of aspirin related UGIB and protective “negative markers” which decreased the risk (Mallah and et al., 2020). Of particular interest, rs689466 T > C, a SNP in the *COX-2* gene was associated with an increased risk of UGIB (Mallah and et al., 2020). However, these data are preliminary and need to be replicated in other cohorts.

There is significant literature describing associations between NSAID-induced immune-mediated ADRs and HLA alleles. These associations are with type I (immediate) urticarial and anaphylactic reactions (*HLA-DR11* and aspirin (Quiralte et al., 1999) and also type IV (delayed) reactions such as Stevens-Johnson syndrome/toxic epidermal necrolysis (*HLA-B*73:01* and oxicam (Lonjou et al., 2008)). To the best of our knowledge, there are no reports of HLA associations with NSAID-induced GI toxicity which is reflective of the non-immune mediated nature of the adverse event.

Based on the pharmacogenomic data presented herein, it is reasonable to suggest that evidence for genetic predisposition to NSAID-induced upper GI toxicity is somewhat contradictory. This reflects the complex nature of the etiology of this ADR but also the significant inter-individual variability in non-genetic risk factors. There are a number of factors which may influence inter-individual pre-disposition to NSAID GI and need to be integrated with pharmacogenomics to further our understanding of individual risk. These include, but not limited to: 1) the impact of altered GI physiology and subsequent drug disposition in special groups and the impact of disease physiology (Stillhart et al., 2020), 2) variability in physiological regulation via gastric enteroendocrine cells (Mace et al., 2015) and 3) *Helicobacter pylori* infection which is a significant risk factor for peptic ulceration independent of NSAID use (Huang et al., 2002).

BEYOND THE HUMAN GENOME

Spurred on by the completion of the Human Microbiome Project (2012), growing evidence supports the role of the microbiome in health and disease. Detrimental changes in gut microbiota composition (intestinal microbiota dysbiosis) are suggested as markers of GI pathogenesis in Crohn’s disease (Gevers et al., 2014), UC (Shen et al., 2018), NSAID-induced enteropathy (Montalto et al., 2013; Syer and Wallace, 2014; Rekatsina et al., 2020) and ulcer healing (Blackler et al., 2015). Microbiome heterogeneity may also influence drug response (Structure, function and diversity of the healthy human microbiome, 2012; Forslund et al., 2015; Wu et al., 2017; Ma et al., 2019; Sharma et al., 2019; Doestzada et al., 2018; Zimmermann et al., 2019; Yip and Chan, 2015; Kashyap et al., 2017).

NSAID disposition, therapeutic efficacy and toxicity are influenced by dynamic and complex host-gut microbiota interactions. Gut microbiota may directly modify NSAID chemistry or manipulate host metabolic processes affecting drug pharmacokinetics and pharmacodynamics. NSAIDs may modify gut microbiota composition resulting in dysbiosis (Maseda and Ricciotti, 2020). Rogers and Aronoff (2016) reported differences in gut microbiota profiles between non-users and NSAID-users. Gut microbiome composition also varied with the type of NSAID ingested (Rogers and Aronoff, 2016).

The capacity to intentionally manipulate the microbiota through diet (Dzutsev et al., 2017; Thiele et al., 2017; Ma et al., 2019), antibiotics/antimicrobials (Lanas and Scarpignato, 2006), fecal microbiota transplant (FMT) (Garber, 2015) or administration of selected probiotic strains (Gionchetti et al., 2000; Ulisse et al., 2001; Gionchetti et al., 2003; Montalto et al., 2010; Montalto et al., 2013; Suzuki et al., 2017; Mortensen et al., 2019; Rekatsina et al., 2020) to enhance efficacy and preserve functional mucosal integrity provides potential therapeutic value for various GI diseases. Recent developments in metaproteomics-based assays offer novel insights into microbiome absolute abundance and functional responses to drugs (Li and et al., 2020). Deployment of next generation sequencing technologies to identify predictive, diagnostic, and prognostic biomarkers need to be further investigated to determine their role in NSAID-induced GI pathology.

FUTURE OPPORTUNITIES AND CLINICAL IMPLEMENTATION

Further research into genetic risk factors predisposing individuals to NSAID-induced upper GI toxicity is justified. Knowledge gaps remain. Currently, there is a shortfall of genome-wide studies, with candidate gene approaches dominating. Lack of consensus and scarcity of independent replication to validate findings has been problematic in published studies. Given the burden and prevalence of NSAID-induced GI ADRs, this is perplexing. A genome-wide approach would allow for unbiased identification of common and rare variants in both PK and PD related genes but would require a large sample size with detailed phenotyping of cases and controls. Indeed, a variability in phenotype definitions is a further challenge in identifying tractable genetic associations. Thus, focused collaborative efforts to standardize phenotype definitions, as shown with other ADRs (Carr et al., 2017; Pirmohamed et al., 2011; Alfirevic et al., 2014; Nicoletti and et al., 2020; Aithal et al., 2011; Behr et al., 2012; Pirmohamed et al., 2011) should be encouraged, drawing inspiration from an adapted 'consensus approach' (Pirmohamed et al., 2011).

CONCLUSION

The pathogenesis of NSAID-induced GI toxicity is complex. PGx is a useful tool to improve pharmacotherapy, and aims to shift the paradigm of dosing regimens being extrapolated to entire populations (Jaccard et al., 2020). Interrogation of genetic factors which predispose individuals to NSAID-induced upper GI toxicity offers unquestionable benefit: pre-emptive testing minimizes the risks of ADRs, informing clinical practice guidelines and therapeutic recommendations to enhance pharmacotherapy (Macías et al., 2020; Theken et al., 2020). To date, the *CYP2C* locus has been shown to be important in some but not all studies. Taken together with the fact that some NSAIDs are only partially metabolized by CYP2C9, but still cause PUD, it can be concluded that *CYP2C* genetic variants are neither necessary nor sufficient to predispose to NSAID-induced PUD, but the presence of low activity *CYP2C9* alleles in a patient given a CYP2C9-metabolised NSAID may increase the risk of PUD. Further work however is also required to identify novel genetic predisposing factors using genome-wide approaches but this will require larger numbers of well phenotyped patients.

Another factor to consider is that as our population continues to age, the prevalence of multimorbidity will increase (Uijen and van de Lisdonk, 2008), which will be accompanied by polypharmacy. Multimorbidity and polypharmacy increase the likelihood of drug- and gene-based interactions (Turner and et al., 2020). The elderly are liable to be prescribed NSAIDs, including LDA, because of the high prevalence of cardiovascular disease and arthritis. The risk of drug-drug interactions with concomitantly administered drugs is likely to be increased in the elderly: these may occur at both pharmacokinetic, (e.g. inhibition of CYP2C9 metabolism) and pharmacodynamic, (e.g. use of NSAIDs and corticosteroids) levels, and may thus contribute to the increased risk of upper GI toxicity. Thus with prolific NSAID use in the over 65 year olds, combinations of risk factors will be common and cumulative, increasing the risks of NSAID-induced ADRs (Laine et al., 2002). It is likely that these ADRs will increase in prevalence despite the use of gastroprotective therapies such as proton pump inhibitors.

In summary therefore, there is a continuing need to define genetic predisposing factors for NSAID-induced PUD because NSAIDs are very widely used, the occurrence of PUD is associated with a high degree of morbidity and mortality, and it is likely with the change in our age demographics, the problems of NSAID-induced PUD are likely to increase rather than decrease.

AUTHOR CONTRIBUTIONS

DC, LM, and MP all contributed to the concept, content, writing and editing of this manuscript.

Abstract

Infertility affects 10% of reproductive-age women and is extremely heterogeneous in etiology. The genetic contribution to female infertility is incompletely understood, and involves chromosomal and single-gene defects. Our aim in this study is to decipher single-gene causes in infertile women in whom endocrinological, anatomical, and chromosomal causes have been excluded. Our cohort comprises women with recurrent pregnancy loss and no offspring from spontaneous pregnancies (RPL, $n=61$) and those who never achieved clinical pregnancy and were referred for in vitro fertilization [primary infertility (PI), $n=14$]. Whole-exome sequencing revealed candidate variants in 14, which represents 43% of those with PI and 13% of those with RPL. These include variants in previously established female infertility-related genes (*TLE6*, *NLRP7*, *FSHR*, and *ZP1*) as well as genes with only tentative links in the literature (*NLRP5*). Candidate variants in genes linked to primary ciliary dyskinesia (*DNAH11* and *CCNO*) were identified in individuals with and without systemic features of the disease. We also identified variants in genes not previously linked to female infertility. These include one homozygous variant each in *CCDC68*, *CBX3*, *CENPH*, *PABPC1L*, *PIF1*, *PLK1*, and *REXO4*, which we propose as candidate genes for infertility based on their established biology or compatible animal models. Our study expands the contribution of single genes to the etiology of PI and RPL, improves the precision of disease classification at the molecular level, and offers the potential for future treatment and development of human genetics-inspired fertility regulators.

Keywords Primary ciliary dyskinesia · Primary infertility · Preimplantation embryonic lethality · Meiotic arrest · Fertilization failure · Recurrent pregnancy loss

Introduction

Infertility is a relatively common reproductive phenotype that affects 10–15% of couples worldwide. In the US alone, it is estimated that 7.7 million women will be diagnosed with infertility in 2025 (Stephen and Chandra 1998). Primary infertility refers to the inability to achieve clinical pregnancy after 1 year of regular and unprotected sexual intercourse, and this can be due to male and female factors (Zegers-Hochschild et al. 2017). Infertility in female is extremely heterogeneous, which reflects the complex interaction of numerous developmental, hormonal, environmental, and genetic factors (Beke 2019). The usual workup of infertile women includes a careful review of systemic diseases, hormonal assessment, anatomical scans, and karyotyping. Such a workup has a limited yield and leaves many women with the uncomfortable label of idiopathic infertility.

Published online: 14 March 2020

The murine animal model has served as a very helpful mammalian proxy to decipher the molecular basis of female fertility through the systematic inactivation of single genes and investigation of the precise consequences of their deficiencies (Greenhouse et al. 1998). Thousands of such genes have been identified and their roles span the entire spectrum from embryonic ovarian development to maternal factors influencing early embryonic development. Unfortunately, only a very small fraction of these genes have been linked to female infertility in humans, mostly due to the fact that exome and genome sequencing has not yet made inroads in infertility clinics. The ~ 200 genes identified to date should serve as an impetus to continue this line of research, since they demonstrated both clinical and scientific utility. For example, we now know that IVF is futile and should not be pursued in women with biallelic mutations of genes involved in early zygote cleavage such as *TLE6* (Alazami et al. 2015). Furthermore, the identification of infertility-causing variants in the ZP genes sets the stage for the development of novel contraceptives targeting the zona pellucida (Nishimura et al. 2019).

Dominant, recessive, and X-linked variants have all been described in the previous discoveries of female infertility-related genes (Group 2008). The highly consanguineous population of Saudi Arabia is known to be enriched for recessive disorders, and the population structure lends itself to positional mapping, especially when combined with WES (Alkuraya 2014). Indeed, we have previously exploited these advantages to identify *TLE6, PADI6,* and *PATL2* as important determinants in female infertility (Alazami et al. 2015; Maddirevula et al. 2017a, b). Here, we extend this work to a much larger cohort and show a corresponding boost in the identification of variants in both known as well as novel disease genes.

Materials and methods

Human subjects

We recruited cases that presented to our infertility center with either (a) primary infertility (PI) or (b) recurrent pregnancy loss (RPL, ≥ 3 losses) with no offspring from spontaneous pregnancies. Cases with PI were recruited if they met any of the following criteria: (1) positive family history, (2) recurrent low oocyte maturity (RLOM), (3) repeated fertilization failure, (4) recurrent implantation failure, and (5) empty follicle syndrome (EFS). Females with polycystic ovary syndrome (PCOS) were only eligible if there was a documented failure to achieve pregnancy after several ovulation inductions with gonadotropin and intra-uterine insemination (IUI). On the other hand, all cases with recurrent pregnancy loss between April 2018 and Sept 2019 were included. We only included cases whose male partners had normal sperm count according to WHO 5th edition (World Health Organization 2010). *MTHFR* and *F2* genes were screened by commercial genotyping assays and the outcome, along with all other clinical laboratory measurements, is documented in Table S1. We also excluded cases with chromosomal, endocrinological or anatomical causes. We defined pregnancy loss ≥ 10 weeks' size with a fetus (≥ 33 mm) on ultrasound as fetal loss, intra-uterine pregnancy loss with an embryo without cardiac activity on ultrasound as embryonic loss, and pregnancy demise based on decreasing serum or urinary β-hCG levels without an ultrasound evaluation as biochemical pregnancy loss (Table S1). Informed consent was obtained from all participants and blood samples were collected in EDTA tubes for genomic DNA extraction and subsequent analysis. This study was approved by the local IRB (KFSHRC RAC# 2140016 and 2121053).

Positional mapping, exome sequencing (ES), and variant prioritization

ES was performed on the index patient of each family as described before (Monies et al. 2017). Given the high degree of consanguinity in the study population, we prioritized variants that are within the autozygome. To combine positional mapping with ES, we employed the method previously described to call the autozygome using ES variants (Monies et al. 2017). We first searched for candidate variants in genes with listed Online Mendelian Inheritance in Man (OMIM) phenotypes. If none were identified, we searched for candidate variants in genes with tentative links to infertility based on their biological roles or corresponding animal models. We followed the ACMG guidelines for variant classification, and only considered variants that are absent or very rare (MAF < 0.00001) in gnomAD and 2379 ethnically matched exomes and had a CAD score of > 15.

Results

Clinical phenotypes

Our cohort comprises women with RPL with no offspring from spontaneous pregnancies ($n = 61$) and those who never achieved clinical pregnancy and were referred for IVF (PI, $n = 14$). Details of their phenotypes are shown in Table S1.

Identification of single-gene causes of female with infertility and RPL

Variants that are potentially relevant to the various phenotypes of female infertility were identified in 18.66% of cases

($n=14$), including eight variants that are pathogenic/likely pathogenic according to the ACMG classification (Fig. 1; Table 1). A breakdown by phenotype revealed that we identified variants in 43% ($n=6$) of PI and 13% ($n=8$) of RPL patients. These variants are further described below.

1. Genes with established links to PI or RPL:
    - (i.) *TLE6*: We identified a homozygous truncating variant NM_024760.2:c.436_437del;p.(Lys146Glufs*51) in an individual with history of four biochemical pregnancies. Only fragmented embryos could be seen following IVF (Fig. 2a; Supplementary Video 1). This is a gene already linked to preimplantation embryonic lethality (Alazami et al. 2015).
    - (ii.) *NLRP7*: This gene is already linked to recurrent hydatidiform mole. In an individual with recurrent molar pregnancy who sought treatment, we observed no pregnancy following three intra-uterine insemination attempts. From two IVF cycles, 12 oocytes were retrieved. Six were intra-cytoplasmic sperm injected, but none was fertilized. The other six were inseminated by IVF and displayed three pronuclei, which predict the development of hydatidiform mole (Fig. 2b). This individual was found to have a homozygous truncating variant in *NLRP7*: NM_206828.3:c.1857_1858del;p.(Lys619Asnfs*18).
    - (iii.) *ZP1*: We encountered one individual with empty follicle syndrome. Upon combined stimulation with rFSH and hMG, she developed 22 follicles (> 10 mm); however, following ovum pickup, no oocytes were found (Fig. 2c). WES revealed a homozygous truncating variant in *ZP1*: NM_207341.3:c.1168delA;p.(Ile390Phefs*10). This gene is already linked to oocyte maturation defect (OMIM: 615774).
    - (iv.) *FSHR*: This gene is already linked to ovarian failure. An individual who is homozygous for the likely deleterious variant

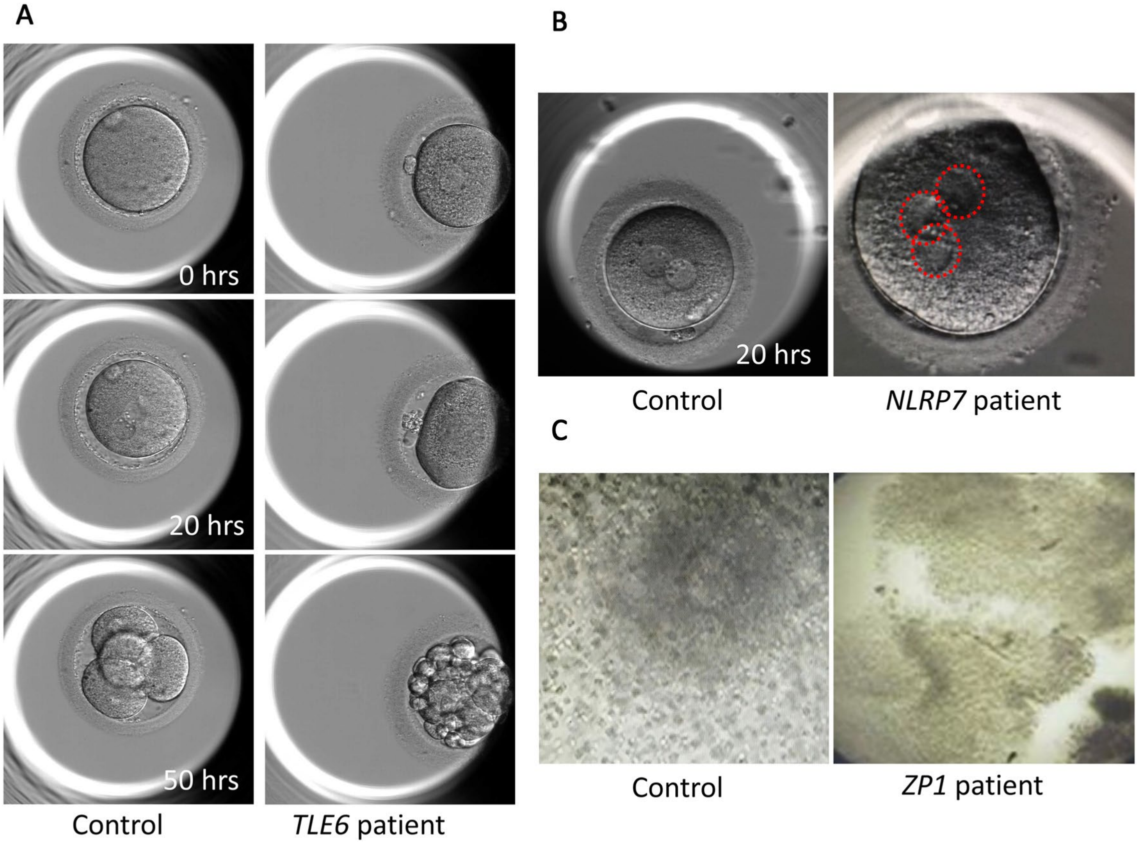

Fig. 2 **a** Oocytes form a patient with *TLE6* mutation. Control and patient oocytes at 0 h after sperm injection are shown. At 20 h, patient oocyte displays very faint two pronuclei in contrast to control. At 50 h, patient oocyte displays four-cell blastomere with heavy fragmentation in contrast to control. **b** Oocyte from a patient with *NLRP7* mutation exhibiting three pronuclei at 20 h in contrast to control. **c** A patient with a mutation in *ZP1* displaying cumulus-like cells with no oocyte in contrast to control

NM_000145.3:c.1121T>A;p.(Ile374Asn) presented with 22 follicles (<5 mm) at baseline ultrasound scan. Ovarian stimulation was continued for 25 days; however, no follicular growth was observed (all remained <5 mm in size). Her two infertile sisters reported a similar history of poor follicular growth when treated in other centers and shared the same homozygous variant.

2. Genes with tentative links to PI or RPL:

   (i.) *NLRP5*: A recent report described *NLRP2* and *NLRP5* variants in individuals with early embryonic arrest (Mu et al. 2019). We identified a PI individual who had two failed IVF cycles. In the first cycle, 28 oocytes were obtained, 14 of which were assigned for intracytoplasmic sperm injection (ICSI). Eight of these were matured; however, upon ICSI, none were fertilized. The other 14 oocytes were inseminated by IVF, but there was also no sign of fertilization. In the second cycle, 18 oocytes were obtained, 6 of which were matured; however, none were fertilized. ES revealed a homozygous truncating variant *NLRP5* (NM_153447.4:c.2274_2275del;p.(Trp759Aspfs*4), thus lending further support to the previously published preliminary association.

   (ii.) PCD genes: Although male infertility is a well-established aspect of the primary ciliary dyskinesia (PCD) phenotype, female infertility in PCD is much less clear (Raidt et al. 2015). In our cohort, we identified two individuals with homozygous likely deleterious variants in PCD genes *DNAH11* and *CCNO*. Only the individual with a homozygous truncating variant in *CCNO* presented with a classical PCD phenotype, whereas that with the *DNAH11* variant presented with PI only (Table S1). Interestingly, IVF was pursued in both patients. The patient with *CCNO* variant had one fresh and two frozen embryo transfer cycles, and one of the latter resulted in an ectopic pregnancy. The patient with *DNAH11* had three cycles of IVF and had one clinical pregnancy that, unfortunately, ended in a spontaneous loss during first trimester.

3. Genes not known to cause PI or RPL in humans:

    (i.) *CCDC68*: The encoded centrosome-binding protein is necessary for the hierarchical assembly of subdistal appendage (SDA), which in turn is required for the anchoring of microtubules in interphase cells (Huang et al. 2017). A 35 year old individual who had two recurrent miscarriages and had a baby through IVF was found on WES to have a homozygous truncating variant NM_001143829.1:c.775dupA;p.(Ser259Lysfs*12). Interestingly, this same variant was also found in our lab's collection in the homozygous state in another individual who had a history of recurrent miscarriages. However, she was not eligible for inclusion in this study, because she eventually had a term pregnancy.

    (ii.) *CBX3*: The encoded protein HP1 gamma plays an important role in regulating the cell cycle in primordial germ cells (PGCs), such that *Cbx3*$^{-/-}$ mouse embryos are depleted in PGCs with resulting sterility phenotype in adult males and females (Abe et al. 2011; Brown et al. 2010). We identified a homozygous potentially splicing variant *CBX3* (NM_007276.4:c.330+3A>G) in an individual with recurrent pregnancy loss and history of two failed IVF cycles.

    (iii.) *PABPC1L*: This poly(A)-binding protein is required for oocyte maturation and its deficiency causes female infertility in mouse (Guzeloglu-Kayisli et al. 2012). We identified a homozygous likely deleterious variant in *PABPC1L* (NM_001372179.1:c.77T>A;p.(Met26Lys)) in a woman whose infertility phenotype resembles that of *Pabpc1l*$^{-/-}$ mouse. During her IVF cycles, 18 oocytes were retrieved and subjected to IVF and ICSI. Nine oocytes were assigned to ICSI, but eight were at germinal vesicle stage and only one showed polar body and failed to fertilize following ICSI. Similarly, nine oocytes were assigned to IVF, and only two showed polar body on the next day without any sign of fertilization. The remaining oocytes were at germinal vesicle stage.

    (iv.) *CENPH*: Complete deficiency of this kinetochore protein is lethal in zebrafish and mice due to accelerated chromosome missegregation-induced apoptosis. Thus, the homozygous likely deleterious missense NM_022909.3:c.635T> C;p.(Ile212Thr) variant which we identified in one individual who presented with eight biochemical pregnancy losses and one fetal loss may be relevant as a germline-restricted phenotype akin to that observed with BUB1B (Baker et al. 2004). Interestingly, embryonic arrest was noted during her IVF treatment. Nineteen oocytes were obtained 12 of which were at metaphase II stage. Following injection, 11 oocytes were fertilized. Six embryos showed extensive fragmentation and arrest at different cleavage stage. Only one embryo reached the eight-cell stage and was transferred along with another seven-cell embryo, but no pregnancy was established.

    (v.) *PLK1*: Similarly to *CENPH, PLK1* is recruited to the kinetochore and is required for proper chromosomal segregation during cell division (Hood et al. 2012). Indeed, several papers describe an essential role by *PLK1* in oocyte development (Pahlavan et al. 2000; Solc et al. 2015; Tong et al. 2002). Again, complete deficiency is lethal and accompanied by increased aneuploidies (Lu et al. 2008), so we propose a germline-restricted phenotype in the individual with a homozygous variant NM_005030.3:c.128T>C;p.(Val43Ala). This individual presented with recurrent pregnancy loss. She had six intra-uterine inseminations, and while three were cancelled due to poor response, bleeding, and risk of hyper stimulation, she did conceive from one of the other three attempts. However, no fetal heartbeat was detected and the pregnancy was spontaneously aborted.

    (vi.) *PIF1*: The encoded helicase is highly conserved and is required to suppress DNA damage at G-quadruplex motifs (Paeschke et al. 2011). A very recent paper describes a *pif1*$^{-/-}$ fly model in which females failed to produce viable progeny (Kocak et al. 2019). This could be relevant to our finding of a homozygous NM_025049.3:c.506C>T;p.(Thr169Ile) variant in an individual with recurrent pregnancy loss (16 embryonic losses and 3 biochemical pregnancy losses).

    (vii.) *REXO4*: Very little is known about the encoded RNA exonuclease, but we opted to highlight the homozygous truncating variant NM_001279350.1:c.253C>T;p.(Gln85*) because of its role in estrogen receptor signaling (Krishnamurthy et al. 2011), which suggests a potential role in the affected individual with recurrent pregnancy loss (two biochemical pregnancy and one embryonic loss).

Discussion

The growing number of genes implicated in Mendelian forms of female infertility mirrors what has long been appreciated in animal models, i.e., many genes are required for normal fertility in females. While previous studies have focused on the role of ES in uncovering single-novel causes, this study seeks to provide a more comprehensive overview of the outcome of applying WES in women with various infertility phenotypes. We had excluded chromosomal aberrations, because these are routinely screened for, at least in women with recurrent miscarriage where they are seen in 12% of the couples, although not always uncovered by routine methods (Dong et al. 2019). Despite the relatively small cohort size, our approach revealed potential single-gene causes in a substantial minority (18.7%) not only in established genes, but also in genes with only tentative or even no link to human female reproduction. These variants spanned the spectrum of reproductive phenotypes from failure to produce oocytes to those with recurrent fetal losses, which increases the relevance of our findings to future studies of female infertility. Importantly, our results highlight that the distinction between the two groups of PI and RPL can be challenged. For example, when we first reported the identification of a founder Saudi variant in *TLE6*, the phenotype of the two original families was very consistent and comprised failure of the zygote to undergo first cleavage, thus representing the earliest known form of embryonic lethality in humans (Alazami et al. 2015). *TLE6* is one of several proteins that constitute the subcortical maternal complex (SCMC), and mutations in other components of SCMC were found to cause cleavage or early embryonic arrest following IVF (Wang et al. 2018). The woman which we report in this study with recurrent pregnancy loss and a homozygous truncating variant in *TLE6* demonstrates that oocytes depleted for *TLE6* have the capacity to undergo several post-fertilization divisions prior to arrest, which is consistent with what was observed in *Tle6*-/- mice (Yu et al. 2014).

The variant which we identified in *FSHR* in three sisters with failure of follicular growth and maturation is another example of phenotypic expansion. Thus far, only three OMIM phenotypes are listed for *FSHR*: ovarian dysgenesis 1 (OMIM: 233300), ovarian hyperstimulation syndrome (OMIM: 608115), and ovarian response to FSH stimulation (OMIM: 276400). Here, we observe a phenotype of normal looking ovaries that lack normal folliculogenesis despite stimulation with resulting loss of negative feedback and elevated LH (Luteinizing hormone) and FSH (follicle-stimulating hormone), but with normal secondary sexual characteristics. This overlaps with the phenotype originally reported in 1998 by Beau et al. who described an Armenian woman with secondary amenorrhea, high FSH levels, and normal-sized ovaries that lacked maturing follicles or corpus luteum, and was found to have a compound heterozygous mutation in *FSHR* (Beau et al. 1998). A third example of phenotypic expansion is our patient with a homozygous variant in *ZP1*. The typical phenotype of *ZP1*-related infertility is lack of zona pellucida (Huang et al. 2014). However, in our patient, no oocyte was retrieved after prolonged stimulation, thus confirming the empty follicle phenotype in described very recently (Dai et al. 2019; Sun et al. 2019; Yuan et al. 2019). Other examples of previously published links that we lend support to through our study are the novel homozygous variant in *NLRP5*, which was only recently linked to human female infertility with early embryonic arrest (Mu et al. 2019). Our patient's phenotype of embryonic arrest at the four-cell stage, therefore, seems to confirm this association. NLRP family proteins are abundant in oocytes, play critical roles in human reproduction, and are associated with multilocus imprinting disturbance. Biallelic mutation in *NLRP7* is known to cause recurrent hydatidiform mole (OMIM: 231090), and we were able to observe the formation of three pronuclei in oocytes from a woman with a homozygous *NLRP7* variant in this study.

Motile cilia have an established role in the clearing of respiratory epithelium and in sperm motility, the two main physiological functions that are lost in patients with primary ciliary dyskinesia (PCD). Despite the identical appearance of motile multicilia in the ovarian ducts to the respiratory epithelium, establishing female infertility as a phenotypic aspect of PCD has been challenging (Raidt et al. 2015). A large epidemiological study, however, lends credence to the original observations that female infertility is, indeed, more common in PCD patients (Vanaken et al. 2017). In fact, the two PCD genes we found mutated in women with infertility in this study (*DNAH11* and *CCNO*) were also found to be mutated in infertile women in that study. Our finding also seems to suggest that caution must be exercised before excluding the possibility of PCD in an infertile woman who lacks the typical respiratory presentation, which is also supported by the finding of PCD gene mutations in males with non-syndromic infertility.

In conclusion, our data support the use of WES to explore monogenic causes of female infertility beyond chromosomal causes. While this study was performed on a research basis, we believe that the growing number of monogenic causes of female infertility identified by this and other studies will eventually spur the clinical adoption of WES for these patients. The clinical utility of making a genetic etiology can be seen in the examples of monogenic forms that not amenable to treatment with IVF techniques, thus saving these women and their physicians' expensive IVF cycles that can be deemed futile by the genetic diagnosis. We also believe this line of research which will reveal novel drug targets for the development of new fertility regulators beyond the currently limited hormonal targets with their known side effects.

Abstract

Background: Clinical interpretation of genetic variants in the context of the patient's phenotype is becoming the largest component of cost and time expenditure for genome-based diagnosis of rare genetic diseases. Artificial intelligence (AI) holds promise to greatly simplify and speed genome interpretation by integrating predictive methods with the growing knowledge of genetic disease. Here we assess the diagnostic performance of Fabric GEM, a new, AI-based, clinical decision support tool for expediting genome interpretation.

Methods: We benchmarked GEM in a retrospective cohort of 119 probands, mostly NICU infants, diagnosed with rare genetic diseases, who received whole-genome or whole-exome sequencing (WGS, WES). We replicated our analyses in a separate cohort of 60 cases collected from five academic medical centers. For comparison, we also analyzed these cases with current state-of-the-art variant prioritization tools. Included in the comparisons were trio, duo, and singleton cases. Variants underpinning diagnoses spanned diverse modes of inheritance and types, including structural variants (SVs). Patient phenotypes were extracted from clinical notes by two means: manually and using an automated clinical natural language processing (CNLP) tool. Finally, 14 previously unsolved cases were reanalyzed.

Results: GEM ranked over 90% of the causal genes among the top or second candidate and prioritized for review a median of 3 candidate genes per case, using either manually curated or CNLP-derived phenotype descriptions. Ranking of trios and duos was unchanged when analyzed as singletons. In 17 of 20 cases with diagnostic SVs, GEM identified the causal SVs as the top candidate and in 19/20 within the top five, irrespective of whether SV calls were provided or inferred ab initio by GEM using its own internal SV detection algorithm. GEM showed similar performance in absence of parental genotypes. Analysis of 14 previously unsolved cases resulted in a novel finding for one case, candidates ultimately not advanced upon manual review for 3 cases, and no new findings for 10 cases.

Conclusions: GEM enabled diagnostic interpretation inclusive of all variant types through automated nomination of a very short list of candidate genes and disorders for final review and reporting. In combination with deep phenotyping by CNLP, GEM enables substantial automation of genetic disease diagnosis, potentially decreasing cost and expediting case review.

Background

A central tenet of genomic medicine is that outcomes are improved when symptom-based diagnoses and treatments are augmented with genetic diagnoses and genotype-differentiated treatments. Worldwide, an estimated 7 million infants are born with serious genetic disorders every year [1]. The last decade witnessed a huge increase in the catalog of genes associated with Mendelian conditions, from about 2300 in 2010 [2], to over 6700 by the end of 2020 [3]. The translation of that knowledge, in conjunction with major improvements in WES and WGS and downstream analytical pipelines, has enabled increased rates of diagnosis, from about 10%, with single gene tests, to over 50% [4]. While limitations of read alignment and variant calling were major obstacles to early clinical implementations of WES and WGS [5], they have been largely removed by algorithmic advances, hardware acceleration, and parallelization through cloud computing [6, 7]. However, clinical interpretation of genetic variants in the context of the patient's phenotype remains largely manual and extremely labor-intensive, requiring highly trained expert input. This remains a major barrier to widespread adoption and contributes to continued low rates of genomic testing for patients with suspected genetic disorders despite strong evidence for diagnostic and clinical utility and cost effectiveness [8].

The major challenge for genome-based diagnosis of rare genetic disease is to identify a putative disease-causing variant amid approximately four million benign variants in each genome, a problem akin to finding a needle in a haystack [9]. Clinical genome interpretation is, by necessity, performed by highly trained, scarce, genome analysts, genetic counselors, and laboratory directors [10]. For an average of 100 variants for review per case [11], this translates to 50–100 h of expert review per patient [10]. In practice, this has led to review of only about 10 variants per case, which somewhat defeats the purpose of genome-wide sequencing.

The genome interpretation process consists of iterative variant filtering, coupled with evidence-based review of candidate disease-causing variants [12]. This process was almost entirely manual until the advent of variant prioritization algorithms, such as Annovar [13] and VAAST [14], and was later improved by the integration of patient phenotypes in analyses, e.g., Phevor [15], Exomiser [16], Phen-Gen [17], Phenolyzer [18], and more recently Amelie [19]. While these tools accelerate review times, their stand-alone performance has been insufficient for widespread clinical adoption, in part due to their inability to appropriately interpret structural variants (SVs). SVs account for over 10% of Mendelian disease [20, 21], and about 20% of diagnoses in routine neonatal intensive care unit (NICU) [22] and pediatric patients [23]. Unified methods for prioritization of SVs, SNVs, and small indels are a fundamental requirement for further automation of genome interpretation.

The use of artificial intelligence (AI) has made significant inroads in healthcare [24], and a new class of genome interpretation methods [19, 25–28] are being developed with the promise of removing the interpretation bottleneck for rare genetic disease diagnosis through electronic clinical decision support systems (eCDSS) [29]. Speed and accuracy of interpretation are particularly important for seriously ill children in the NICU [27], where diagnosis in the first 24–48 h of life has been shown to maximally improve health outcomes [30]. The settings and extent to which AI facilitates diagnosis are still being investigated [27, 28]. Issues include what types of AI methods are most suitable (e.g., Bayesian networks, decision trees, neural nets [31]); how they compare with current variant prioritization approaches in terms of accuracy; their diagnostic performance across different clinical scenarios and variant types; their potential to offer new forms of decision support; and how well they integrate with automated patient phenotyping and clinical decision making [27, 28, 32].

Algorithmic benchmarking in this domain is no simple matter. Hitherto, most attempts have used simulated cases (created by adding known disease-causing variants to reference exomes and genomes), included only a few cases, derived from a single center, or were limited to certain variant types [17, 33, 34]. Such benchmarking is inherently limited, as it is not representative of the true diversity of genetic diseases and variant types (e.g., by omitting cases with causal SVs), and provide no means to evaluate the impact of different sequencing and variant calling pipelines on performance.

Here we describe and benchmark the diagnostic performance of Fabric GEM (hereafter referred to as "GEM"), a new AI-based eCDSS, and compare it to current variant prioritization approaches using a diverse cohort of retrospective pediatric cases from the Rady Children's Institute for Genomic Medicine (RCIGM). These cases are largely comprised of seriously ill NICU infants; all were diagnosed with Mendelian conditions following WGS (or, in a few cases, WES), using a combination of filtering and variant prioritization approaches. These real-world cases encompass the breadth of phenotypes and disease-causing variants, including pathogenic SVs. We then sought to replicate the diagnostic performance of GEM in a second set of affected, diagnosed, and undiagnosed children outside the NICU. They were collected from five different academic medical centers, mostly consisting of WES, to examine the generalizability of GEM's diagnostic performance to other sequencing, variant calling pipelines, and clinical settings. Finally, we reanalyzed a set of previously negative RCIGM cases to evaluate the ability of GEM to identify new diagnoses without suggesting numerous false positives that would lead to time-consuming case reviews. Our results show that rapid, accurate, and comprehensive WGS- and WES-based diagnosis is achievable through integration of new data modalities with algorithmic innovations made possible by AI.

Methods

Patient selection, phenotyping, and specimen sequencing

This retrospective study was designed to provide benchmark data to test the GEM eCDSS. We compiled 119 cases from Rady Children's Hospital (the *Benchmark* cohort), consisting of mostly NICU admissions, and 60 additional cases from five academic medical centers (the *Validation* cohort), which consisted mostly of referrals from genetic clinics and none included causal structural variants, as described below.

Rady Children's Hospital

In total, 119 cases with primary findings, deemed definitively solved using previously published methods [27, 30, 35], and 14 negative cases, were sequenced as part of the rapid-WGS (rWGS) sequencing program at the Rady Children's Hospital Clinical Genome Center. These cases where a sample of convenience, drawn from the first symptomatic children who were enrolled in four previously published studies that examined the diagnostic rate, time to diagnosis, clinical utility of diagnosis, outcomes, and health care utilization of rWGS between 26 July 2016 and 25 September 2018 at Rady Children's Hospital, San Diego, USA. One of the studies was a randomized controlled trial of genome and exome sequencing (ClinicalTrials.gov identifier: NCT03211039) [30]; the others were cohort studies (ClinicalTrials.gov identifiers: NCT02917460, and NCT03385876) [35–40]. All subjects had a symptomatic illness of unknown etiology in which a genetic disorder was suspected, had a Rady Children's Hospital Epic EHR, and that had clinical phenotype descriptions expressed as human phenotype ontology terms both manually curated by clinicians and automatically extracted by CNLP (Additional file 1: Table S1).

WGS (or in a few instances WES) was performed as previously described [35, 40]. Briefly, PCR-free WGS was performed to an average of 40× coverage in the Illumina HiSeq 2000, HiSeq 4000, and NovaSeq 6000 sequencers. Alignment and sequence variant calling were performed using the Illumina DRAGEN software, while copy number variation was identified through an approach that integrates the tools Manta [41] and CNVnator [42]. Structural variants were then filtered for recurrent artifacts observed in previous non-affected cases and only included in the input VCF file if they overlap a known disease gene (OMIM). All variants reported as primary findings were validated orthogonally by Sanger sequencing. In the case of trios, de novo origin of reported variants was established by comparing to their parents' data. In some older cases, SV calling was not performed; any causal SVs therein were identified by an orthogonal CGH microarray or manual inspection of alignments. In what follows, we refer to these 119 cases with primary findings as the *Benchmark* cohort, and the 14 negative cases as the *Unsolved* cohort.

Boston Children's Hospital

Eleven cases (all single probands) from the Beggs Lab, Congenital Myopathy Research Program laboratory, and Manton Center for Orphan Disease Research at Boston Children's Hospital were included in the analysis [43–48].

Libraries (TruSeq DNA v2 Sample Preparation kit; Illumina, San Diego, CA) and whole-exome capture (EZ Exome 2.0, Roche) were performed according to manufacturer protocols from DNA extracted from blood samples. WES was carried out on an Illumina HiSeq 2000. Reads were aligned to the GRCh37/hg19 human genome assembly using an in-house assembler. Variants were called using Gene Analysis Toolkit (GATK) version 3.1 or higher (Broad Institute, Cambridge, MA) and were Sanger confirmed by the Boston Children's Hospital IDDRC Molecular Genetics Core Facility.

Christian-Albrechts University of Kiel

Twelve cases (all single probands) from the Institute of Clinical Molecular Biology (IKMB) were included in the analysis [49–55].

Illumina's Nextera/TruSeq whole-exome target capture method was applied. WES was carried out on the Illumina HiSeq/NovaSeq platforms. Reads were aligned to the GRCh37/hg19 human genome assembly using BWA-MEM version 0.7.17 and variants called using GATK version 4.1.6.0 (Broad Institute, Cambridge, MA).

HudsonAlpha Institute for Biotechnology

Three cases (two trios and a single proband) from the Clinical Services Laboratory at HudsonAlpha Institute for Biotechnology, including cases from the Clinical Sequencing Evidence-Generating Research (CSER) consortium, were included in the analysis [56–59].

WGS was carried out on an Illumina HiSeq X. Reads were aligned to the GRCh37/hg19 human genome assembly followed by variant calling using the Illumina DRAGEN software version 3.2.8 (Illumina, Inc. San Diego, CA).

Translational Genomics Research Institute

Twenty-three cases (including singletons, duos, trios, and quads) from the Center for Rare Childhood Disorders at The Translational Genomics Research Institute (TGen) were included in the analysis [60, 61].

WES or WGS sequencing was carried out on an Illumina HiSeq 2000, HiSeq 2500, HiSeq 4000, or NovaSeq6000. For WES, the Agilent SureSelect Human All Exon V6 or CRE V2 target capture method was applied. Reads were aligned to reference GRCh37 version hs37d5 and variants called using GATK Haplotype caller version 3.3-0-g37228af (Broad Institute, Cambridge, MA).

Tartu University Hospital

Eleven cases from Tartu University Hospital in Estonia that had undergone WES were included in the analysis [62–64].

Nextera Rapid Capture Exome Kit-i (Illumina Inc.) target capture method was applied. WES was carried out on an Illumina HiSeq2500 sequencer. Reads were aligned to the GRCh37/hg19 human genome assembly using BWA-MEM version 0.5.9 and variants called using GATK Haplotype caller version 3.4 (Broad Institute, Cambridge, MA).

Variant annotation and data sources

All analyses were performed based on the GRCh37 human genome assembly. Variant consequences and annotations were obtained with VEP v.95 [65] utilizing ENSEMBL transcripts version 95 (excluding non-coding transcripts) and selecting the canonical transcript for analysis. Transcript-specific prediction for evaluating variant deleteriousness was calculated with VVP [66], which were also used as input for VAAST [14]. Variants were annotated with ClinVar (version 20200419) [67] ensuring exact position and base match. Gene conditions were extracted from OMIM (version 2020_07) [68] and HPO (obo file dated 2020-08-11) [69]. Gene symbols were harmonized using ENSEMBL and HGNC databases controlling for synonymous gene symbols.

AI-based disease gene and condition prioritization

AI-based prioritization and scoring of candidate disease genes and diagnostic conditions was performed using Fabric GEM [70], which is a commercially available eCDSS part of the Fabric Enterprise platform (Fabric Genomics, Oakland, CA). GEM inputs are genetic variant calls in VCF format and case metadata, including (optional) parental affection status, and patient (proband) phenotypes in the form of Human Phenotype Ontology (HPO) terms. The VCF files can include "small variants" (single nucleotide, multiple nucleotide, and small insertion/deletion variants), and (optionally) structural variants (insertion/deletions of over 50 bp, inversions, and/or copy number variants with imprecise ends). This information can be provided via an application programming interface or manually in the user interface. Data analysis is typically carried out in minutes depending on inputs. GEM outputs are displayed in an interactive report (Additional file 2: Figure S1) that includes a list of candidate genes ranked by the GEM gene score (see below), detailed information of patient variants present in each candidate gene, and conditions associated with each candidate gene ranked by GEM's condition match (CM) score (explained below).

GEM aggregates inputs from multiple variant prioritization algorithms with genomic and clinical database annotations, using Bayesian means to score and prioritize potentially damaged genes and candidate diseases. Briefly, the algorithm parametrizes itself using the proband's called variants as one-time, run-time training data, inferring the states of multiple variables directly from the input variant distribution, e.g., sex. Additional static training parameters were derived from the 1000 Genomes Project [71] and CEPH [72] genome datasets. GEM reevaluates genotype calls and quality scores considering read support, genomic location, proband sex, and potentially overlapping SVs, augmenting the genotype calls with more nuanced posterior probabilities, computing ploidy for each variant. GEM also computes the likelihood that the proband belongs to any of several different ancestry groups using the input genotypes together with gnomAD sub-population variant frequency data [73]. The probabilities of other, internal, variables, conditioned on each state (sex and ancestry, etc.) are then obtained using naive Bayes, controlling for non-independence of variables by calculating a correlation matrix at run time using the proband's data. For example, after conditioning variant scores on ancestry, known inheritance pattern for the gene in question, gene location, and proband sex, GEM may conclude that a de novo variant is unlikely to participate in a disease-causing genotype, even though it is predicted to be highly damaging. Thus, highly damaging and de novo variants, even frameshifting ones, do not automatically receive high GEM scores. GEM uses the same procedure to evaluate and score biallelic genotypes for known and novel disease-gene candidates. The only difference is that the global prior (e.g., relative proportion of known disease genes with autosomal recessive vs. autosomal dominant inheritance patterns), rather than OMIM and HPO support for a particular inheritance pattern at that locus, is used to evaluate possible biallelic cases in novel gene candidates.

GEM's gene scores are Bayes factors (BF) [74]. Analogous to the likelihood ratio test, a Bayes factor presents the $\log_{10}$ ratio between the posterior probabilities of two models, summarizing the relative support for the hypothesis (in this case) that the prioritized genotype damages the gene in which it resides and that explains the proband's phenotype versus the contrapositional hypothesis that the variant neither damages the gene nor explains the proband's phenotype. In keeping with established best practice [74], a $\log_{10}$ Bayes factor between 0 and 0.69 is considered moderate support, between 0.69 and 1.0 substantial support, between 1.0 and 2.0 strong support, and above 2.0, decisive support. A score less than 0 indicates that the counter hypothesis is more likely. For calculating the Bayes posterior $p(M|D)$, the probability of the data given a model $(pD|M)$ is derived from GEM's severity scoring protocol, which includes input from the VAAST and VVP algorithms, and any available prior variant classifications from the ClinVar database. This model is conditioned upon sex, ancestry, feasible inheritance model, gene location, and gene-phenotype priors derived by seeding the provided patient HPO terms to the HPO ontology graph and subsequently obtaining priors for all genes in the HPO and GO ontologies by belief propagation using Phevor's previously described Bayesian network-based algorithm [15]. The prior probability for the model (pM) is based upon known disease associations in the Mendelian conditions databases OMIM and/or HPO with the gene in question.

GEM's Bayes factor-based scoring system is designed for ease of explanation and to speed interpretation. GEM scores are not intended to be definitive, rather they are designed to provide guidance for succinct case reviews carried out by clinical geneticists. Thus, GEM outputs also include several additional scores that provide additional guidance and improve explainability. GEM gene scores, for example, are accompanied by VAAST [14], VVP [66], and Phevor [15] posterior probabilities, conditioned upon the potentially confounding variables of proband sex, gene location, and ancestry, together with common variant genomic and clinical annotations (Additional file 2: Figure S1). These scores further ease interpretation, as they allow users to assess the major drivers of a GEM score and their relative contributions to it.

GEM also provides means to assess the Mendelian conditions associated with putative disease-causing genes as possible diagnoses via its condition match (CM) scores. Like gene scores, CM scores are Bayes factors and are derived from the $\log_{10}$ ratio of the posterior probability that HPO phenotype associations for a given Mendelian condition's HPO are consistent with the proband's phenotype versus the contrapositional hypothesis. For these calculations, the probability of the data, $p(D|M)$, is determined using Phevor's Bayesian algorithm to obtain a probability for each disease, conditioned upon the proband's phenotype. The prior probability for the model, $p(M)$, is the probability that one or more genes associated with the Mendelian condition (as documented in OMIM and/or HPO) contain a damaging genotype as ascertained by GEM's severity scoring protocol. Condition match scores are displayed alongside each gene-associated condition for review (Additional file 2: Figure S7).

Structural variant scoring and ab initio inference by GEM

At run time, GEM infers ab initio the existence of SVs, their coordinates, and their copy numbers (ploidy) in a probabilistic fashion using SNVs, sort indel calls, read depths, zygosity, and gnomAD frequency data. GEM searches the proband's genotypes for evidence of three types of SV: deletions, duplications, and CNVs. Regions exhibiting loss of heterozygosity (LOH), for example, are used as evidence for heterozygous deletions. Genomic spans lacking expected variants, the signature of homozygous deletions, are identified using gnomAD population frequencies [73] to derive point estates that a given gnomAD variant would or would not be ascertained given its population frequency. Further evidence for duplications and deletions is derived from read support, e.g., approximately integer increases or decreases in depth across a region provide support for copy number variation. Point estimates at each site of a small variant call are further conditioned upon provided variables, such as genotype qualities, and inferred ones, such as sex and ancestry, to obtain more refined estimates. High scoring segments and their maximum likelihood start and end coordinates are identified using a Markov model [75]. The results are used to determine the degree of support for external SV calls, and as the basis for GEM's own SV calls. For ease of reporting, ab initio SV calls that overlap an external SV call (default minimum reciprocal overlap of 33%) are replaced in the output by the external SV call as long as they still overlap the relevant scored genes.

Benchmarking variant prioritization with VAAST, Phevor, and Exomiser

We used the Snakemake software [76] to create a workflow that analyzes cases with the VAAST, Phevor, and Exomiser algorithms. This workflow was only applied to the benchmark cohort to enable us to compare the performance of four genome interpretation tools with exactly the same inputs and annotations. The pipeline starts with a VCF file, family structure, affection status, and HPO terms and concludes with the outputs for each of the algorithms. VVP scores were obtained as described above and provided to VAAST as input. VAAST was provided pedigree information and affection status and was run in both dominant and recessive modes with results aggregated. Gene ranks for VAAST are reported for the highest scoring occurrence of the gene from aggregated outputs. Phevor was provided with HPO terms and VAAST scores as inputs. Ranks were selected as described for VAAST.

Exomiser [16] benchmark analyses were run with the same configuration used in the 100,000 Genomes Project [77], specifically (1) using the GRCh37 genome assembly; (2) analyzing autosomal and X-linked forms of dominant and recessive inheritance; (3) allele frequency sources from the 1000 Genomes Project [78], TopMed [79], UK10K [80], ESP, ExAC [81], and gnomAD [73] (except Ashkenazi Jewish); (4) pathogenicity sources from REVEL [82] and MVP [83]; and (5) including the steps failedVariantFilter, variantEffectFilter (remove non-coding variants), frequencyFilter with maxFrequency = 2.0, pathogenicityFilter with keepNonPathogenic = true, inheritanceFilter, omimPrioritiser, and hiPhivePrioritiser.

Exomiser was considered to have identified the diagnosed gene when it was scored as a candidate for any of the utilized modes of inheritance. None of the tools in this analysis were provided a target mode of inheritance (as it is unknown), and so the diagnostic gene rank for Exomiser was determined from its rank within the combined gene candidate list from all modes of inheritance (i.e., the same procedure used for VAAST and PHEVOR). The ranks within the combined list of candidate genes were generated by sorting gene-level candidates from all modes of inheritance on the Exomiser combinedScore in descending order with each candidate gene only added to the list on its first, highest scoring occurrence. Exomiser variant level scoring was not considered for determining candidates or ranking. All Exomiser analyses on the benchmark cohort ran to completion and successfully produced output; however, in 18 cases, Exomiser did not identify the true positive diagnostic gene as a scored candidate (i.e., it was absent from its output). A similar phenomenon was observed in 4 cases using VAAST. For both tools, these cases were considered false negatives.

Impact of deep phenotypes derived from clinical NLP

The utility of HPO terms was investigated by rerunning all analyses from the benchmark cohort with three sets of HPO terms. The motivations for these analyses were first to determine how sensitive GEM is to phenotyping errors; and second, to compare the utility of CNLP-derived descriptions to manual ones. For each case, an HPO terms list was provided that included HPO terms manually curated by the analysis team when the case was originally solved. A second set of HPO terms was generated from NLP analysis of clinical notes related to the case using the CLiX ENRICH software (Clinithink, Alpharetta, GA) [28]. A randomized set of HPO terms was generated for each case whereby the number of HPO terms from the CliniThink analysis case was held constant, and alternate terms were randomly selected from the entire corpus of HPO terms across all samples with each selection probability determined by the number of times that term occurred in the corpus.

Results and discussion

GEM AI outperforms variant prioritization approaches

We benchmarked GEM, an AI-based eCDSS, using a cohort of 119 pediatric retrospective cases from Rady Children's Institute for Genomic Medicine (RCIGM; benchmark cohort). Most of these were critically ill NICU infants who received genomic sequencing for diagnosis of genetic diseases. All had been diagnosed with one or more Mendelian conditions using a combination of manual filtering and variant prioritization approaches ("Methods"). To further validate performance, we also analyzed a second cohort comprised of 60 non-NICU, rare disease patients from five different academic medical centers (validation cohort). Finally, we reanalyzed a set of 14 previously analyzed probands that had remained undiagnosed by WGS. Our goal was to evaluate the ability of GEM to identify new diagnoses in these previously unsolved cases, without providing false positive findings that would result in time-consuming case reviews. To provide context for our performance benchmarks, we also ran three commonly used variant prioritization tools: VAAST [14], Phevor [15], and Exomiser [16].

The benchmark and validation cohorts included singleton probands, parent-offspring trios, different modes of inheritance, and both small causal variants (SNVs, and small insertions or deletions, indels; Table 1; Additional file 1: Table S1) and large structural variants (SV), some of which were causative (Table 2). In these retrospective analyses, we considered the variants, disease genes, and conditions that were included as primary findings in the clinical report as the "gold standard" truth set.

GEM gene scores are Bayes factors (BF) [84]; these were used to rank gene candidates (Additional file 2: Figure S1). BFs are widely used in AI, as they concisely quantify the degree of support for a conclusion derived from diverse lines of evidence. In keeping with established practices [84], a BF of 0–0.69 was considered moderate support, 0.69–1.0 substantial support, 1.0–2.0 strong support, and above 2.0, decisive support [84]. Scores less than 0 indicated support for the counter hypothesis—that variants in that gene were not causal for the proband's disease. GEM outputs also include several annotations and metrics that provide additional, supportive guidance for subsequent expert case review (Additional file 2: Figure S1). Experience has shown that such guidance is critical for adoption by experts who wish to review the evidence supporting automated variant assertions. These include VAAST, VVP, and Phevor posterior probabilities, conditioned upon proband sex, gene location, and ancestry. Annotations include variant consequence, ClinVar database pathogenicity assessments, and OMIM conditions associated with genes. This metadata enables expert users to review the major contributions underpinning a final GEM score. Moreover, GEM prioritizes diplotypes, rather than variants, which speeds interpretation of compound heterozygous variants in recessive diseases (Additional file 2: Figure S1B). Comparison of the diagnostic performance of GEM to variant prioritization methods utilized ranking of the correct diagnostic gene. We assumed that in the case of compound heterozygotes, variant prioritization methods such as Exomiser would rank one variant of the pair highly, leading to identification of the other upon manual review ("Methods").

GEM ranked 97% of previously reported causal gene(s) and variant(s) among the top 10 candidates in the 119 benchmark cohort cases. In 92% of cases, it ranked the correct gene and variant in the top 2 (Fig. 1A). By comparison, the next best algorithm, Phevor, identified 73% of causal variants in the top 10 candidates and 59% in the top 2. GEM, Phevor, and Exomiser prioritize results by patient phenotypes (provided as HPO terms) in addition to variant pathogenicity, whereas VAAST only utilizes genotype data, explaining its lower performance. Thus, these data also highlight that patient phenotypes improve the diagnostic performance of automated interpretation tools.

The benchmark cohort included 3 cases for which two genes were reported to contribute to the patient phenotype. This rate (2.5%) is consistent with previous reports for digenic inheritance [85]. The statistics above use the top ranked genes in these cases, but Additional file 1: Table S3 shows that GEM also ranked the second causal gene among its top candidates, whereas Phevor reported poor ranks in one case, and Exomiser missed the second gene in two out of the three cases.

Table 1 Characteristics of case cohorts. Benchmark cohort, 119 cases total. Validation cohort, 60 cases total. Grand total, 179 cases

	Assay type		Variant type		Proband sex		Pedigree Type		
Mode of inheritance	**WGS**	**WES**	**SNV/Indel**	**SV**	**Male**	**Female**	**Single**	**Duos**	**Trios**
Benchmark cohort									
Autosomal dominant	70	11	66	15	36	45	35	6	40
Autosomal recessive	27	–	23	4	14	13	9	1	17

Table 2 Diagnostic structural variants identified by GEM in the benchmarking cohort (20 out of 119 cases). Structural variants are ranked by GEM based on the genes harbored by the variant and presented alongside other ranked genes with coding SNVs or small indels based on the top scored gene. The asterisk indicates genes that in the literature are candidates for the phenotype of the diagnostic disease/syndrome (as described in OMIM). The results show that GEM can analyze both deletions (del) and duplications (dup) of sizes as small as 4 kb and up to entire chromosome arms, diverse modes of inheritance, pedigree structure, and from either WGS or WES assay data. GEM also automatically identified compound heterozygotes between SVs and SNV/indels (cases 1, 2, and 8). Input SV calls can include breakpoint-based calls (here "SV"), or imprecise CNV calls based on read depth analysis. Notably, GEM can also infer SVs directly from the small variant data when external SV calls are not provided (cases 2, 10, 15, and 17), and score them appropriately, identifying diagnostic variants that in the original cases were found by microarrays and not by sequencing

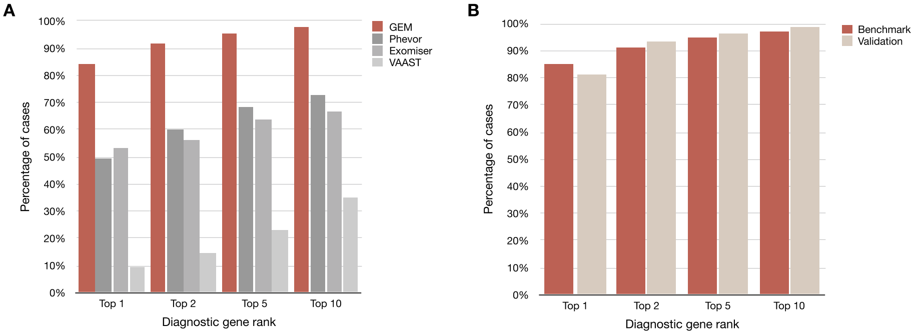

Fig. 1 The diagnostic sensitivity of GEM was greater than the variant prioritization methods Phevor, Exomiser, and VAAST. **A** Proportion of the benchmark cohort of 119 cases where the true causal genes (or variants in the case of causal SVs) were identified among the top 1st, 2nd, 5th, or 10th gene candidates. Patient phenotypes were extracted manually from medical records by clinicians and provided as HPO term inputs to GEM, Exomiser, and Phevor. VAAST only considers variant information. It should be noted that GEM and Phevor ranks correspond to genes, which may include one or two variants (the latter in the case of a compound heterozygote), whereas Exomiser and VAAST ranks were for single variants. In the case of compound heterozygotes, the rank of the top-ranking variant is shown for Exomiser and VAAST. **B** Comparison of GEM performance in the validation cohort (excluding SV cases) versus the validation cohort (comprised of 60 rare genetic disease cases from multiple sources)

Next, we investigated whether the diagnostic performance of GEM extended to Mendelian diseases other than those of NICU infants, such as patients with later disease onset, less severe presentations, or with data produced by other variant calling pipelines or outpatient genetic clinics. For these analyses, we compiled a validation cohort largely consisting of WES cases from five different academic medical centers (Table 1; Additional file 1: Table S2). The diagnostic performance of GEM in the validation cohort was almost identical to that in the benchmark cohort (Fig. 1B). These data demonstrated that the diagnostic performance of GEM was not dependent of disease severity, age of onset, or genomic sequencing or variant detection methods.

An implication of these findings is that GEM achieved 97% recall (true positive rate) by review of 10 genes, whereas the other tools had ≤ 78% recall by similar review (Fig. 1, Additional file 2: Figure S2). In part, this difference reflected the unique ability of GEM to prioritize SVs. Excluding SV cases, GEM, Phevor, and Exomiser achieved recall of 97%, 83%, and 76%, respectively, by review of 10 genes (Additional file 2: Figure S3A). Furthermore, VAAST and Exomiser failed to provide rankings for 4 and 18 true positive variants, respectively. Exclusion of false negatives and SV cases increased the top 10 recall of Exomiser to 93% (Additional file 2: Figure S3B), in agreement with previous reports [86]. These data show the importance of including all types of cases and causal variants in benchmarking to avoid overestimation of diagnostic performance in real-world clinical applications.

Scoring of structural variants increases diagnostic rate

A major barrier to the incorporation of SV calls into genome diagnostic interpretation, whether manual or using eCDSS, is their low precision (high false positive, FP, rates) using short read alignments, with typical FP rates of 20–30% [87, 88]. This leads to overwhelmingly time-consuming, manual assessment of event quality and significance for large numbers of SVs. GEM minimizes the effect of low precision by scoring SVs either with SV calls provided in the proband's input VCF file, and/or by inferring ab initio their existence from metadata associated with SNV and indel calls ("Methods"; see below). The benchmark cohort included 20 cases in which SVs were reported to be causative, reflecting a similar incidence to that in real-world experience (Fig. 1A, Table 2) [20–23]. In 17 of these, the causative SV was ranked first by GEM. In two, it was ranked second, and in one it was listed fourth, demonstrating that GEM retains adequate diagnostic performance with imprecise SV calls. The disease-causing SVs in the benchmark set ranged from small (4 kb) to very large (e.g., entire chromosome arms). In three cases, the diagnosis was of an autosomal recessive disorder in which the SV was compound heterozygous with a SNV/indel. In each, GEM integrated the two variants correctly, automatically identifying the causative diplotypes (Additional file 2: Figure S5). With regard to the diagnostic specificity of GEM, the mean and median number of gene candidates for these probands with BF > 0 (any support) was 8.7 and 9.5, respectively, which was similar to probands whose VCF files contained no SVs, causative or otherwise.

Large SVs frequently affect more than one gene. For consistency with other variant classes, genes within multigenic SVs are grouped and sorted by GEM based upon the gene-centric Bayes factor score associated with the overlap of the proband phenotype and known Mendelian disorders (if any) associated with them ("Methods"). For example, Additional file 2: Figure S4 shows a case that highlights the practical utility of prioritizing genes harboring causative SVs together with SNVs and short indels in the same report, rather than separately cross-referencing with databases of microdeletion syndromes [89]. While it is often unknown which genes harbored in a pathogenic SV are causal for microdeletion/microduplication syndromes, GEM's gene-by-gene rankings typically agreed with causal gene candidates suggested by the literature (asterisks in Table 2).

By default, GEM evaluates every gene and transcript for the presence of overlapping SVs. Notably, four benchmark cases did not include externally called SVs in their input VCFs (these had been previously diagnosed by manual inspection and orthogonal confirmatory tests; Table 2). Nevertheless, GEM inferred the existence of these four SVs using its ab initio SV identification algorithm and evaluated them jointly with SNVs and indels ("Methods"). To further demonstrate this innovative functionality, we removed all external SV calls from each input VCF file of the 14 WGS cases (as GEMs ab initio SV imputation is currently limited to WGS data) and reran GEM. GEM re-identified 13 of the 14 of the causative SVs. Although GEM's inferred SV termini were imprecise, an overlapping SV of the same class (duplication, deletion, or CNV) and ploidy to that in the original VCF was inferred, and the same high scoring gene and mode of inheritance/genotype (autosomal dominant, simple recessive, or compound heterozygote) was ranked first. SV recall within the top 1, 5, and 10 ranked GEM results were 71%, 86%, and 93%, respectively. The single false negative was a small (4 kb) homozygous deletion. GEM failed to identify this SV because it did not span sites with known variation in the gnomAD database [73], upon which ab initio SV inference is based ("Methods"). With regard to specificity, the mean and median number of results with genes with BF > 0 in these cases was 10.6 and 12.5, respectively. These values differed only slightly from the results obtained using external SV calls (8.7 and 9.5, respectively), despite the fact every gene and transcript was evaluated for the presence of SVs.

Collectively, these results demonstrate the accuracy of GEM's ab initio approach to identification and prioritization of SVs without recourse to external calls and databases of known causative SVs. Thus, GEM compensates, in part, for the low recall of SVs from short-read sequences. If an external SV calling pipeline fails to detect an SV, there is still the possibility that GEM will identify it via this ab initio approach. This capability, together with GEM's ability to accurately prioritize SVs in the context of SNVs and short indels, addresses an unmet need for clinical applications. This characteristic also makes GEM well suited for reanalyses of older cases and/or pipelines lacking SV calling.

Leveraging automated phenotyping from clinical natural language processing

Ontology-based phenotype descriptions, using Human Phenotype Ontology (HPO) terms [69], are widely used to communicate the observed clinical features of disease in a machine-readable format. These lists of terms are usually derived by manual review of patient EHR data by trained personnel, a time-consuming, subjective process. A solution is automatic extraction of patient phenotypes from clinical notes using clinical natural language processing (CNLP) [28, 90]. One challenge has been that CNLP generates many more terms than manual extraction. Thus, manual curation yielded an average of 4 HPO terms (min = 1, max = 12) in the benchmark cohort, while CNLP yielded an average of 177 HPO terms (min = 2, max = 684). Some of the extra CNLP terms are hierarchical parent terms of those observed, raising the concern that their inclusion diminishes the average information content in a manner that could impede diagnosis [27]. To investigate the effect of CNLP-derived HPO terms on GEM's performance, we analyzed the benchmark cohort both with HPO terms extracted by commercial CNLP ("Methods") and manually extracted HPO terms.

Figure 2 shows the distributions and medians for ranks and GEM gene scores of true positives, as well as the number of gene candidates with BF ≥ 0.69 (moderate support), for manual and CNLP terms. The median rank of the causal genes did not significantly differ between CNLP- and manually derived phenotype descriptions (Fig. 2A). The median GEM gene score of true positives was higher with CNLP-derived phenotypes than with manual phenotypes (Fig. 2B). The number of candidates above the BF threshold was higher with manual phenotypes than CNLP (Fig. 2C). CNLP rescued a few true positives with low ranks and negative BF scores compared to manual phenotype descriptions (Fig. 2A, B). These results demonstrate that GEM performs somewhat better with CNLP-derived phenotype descriptions as part of an automated interpretation workflow, than with sparse, manual phenotypes.

Resilience to mis-phenotyping and gaps in clinical knowledge

Given the potentially noisy nature of the CNLP phenotype descriptions, it was important to examine the sensitivity of GEM to mis-phenotyping. To address this question, we randomly permuted CNLP-extracted HPO terms between cases, weighting by term frequency within the cohort, so that every case maintained the same number of HPO terms as CNLP originally provided. Permuting HPO terms resulted in lower gene scores, and several cases would have been lost for review had the gene score threshold of BF ≥ 0 still been used,

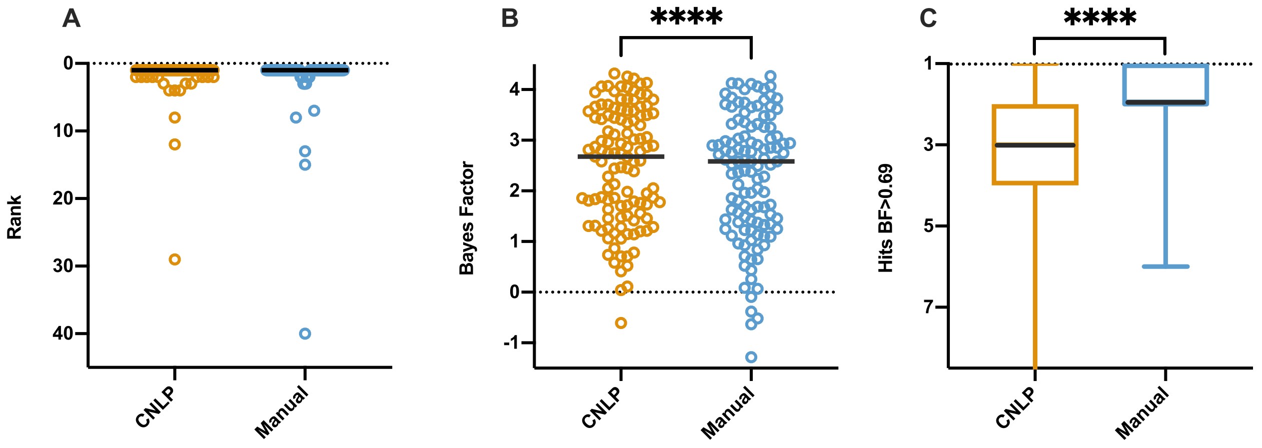

Fig. 2 Comparison of GEM performance with manually curated and CNLP-derived HPO terms in the benchmark cohort. Distribution of ranks for causal genes (**A**); GEM Bayes factors for causal genes (**B**); and number of candidates (hits) at BF ≥ 0.69 threshold (moderate support) (**C**). The black line in the graphs denotes the median. The asterisks represent statistical difference between the groups with $p < 0.0001$ from a two-tailed Wilcoxson matched pairs signed rank test (ranks showed no statistically significant difference)

but ranks are unaffected (98% in top 10; Fig. 3). This represented lower bound estimates, as actual mis-phenotyping (short of data tracking issues) would be much less. It is also worth noting that even using randomly permuted phenotype descriptions, GEM's performance still exceeded that of Phevor and Exomiser using the correct phenotypes (Additional file 2: Figure S2). We therefore conclude that GEM is resilient to mis-phenotyping.

We also evaluated the impact of gaps in clinical knowledge on GEM performance by withdrawing annotations from a key clinical database, ClinVar. Absence of ClinVar annotations had minimal impact in ranking, although it reduced median gene scores (1.1 vs. 2.7), resulting in 9 cases no longer meeting the minimum Bayes factor threshold ≥ 0 (any support; Fig. 3). Clearly, ClinVar provided GEM with valuable information. Nonetheless, without ClinVar, GEM's top 10 maximal recall (88%) still exceeded that of Phevor (72%) and Exomiser (65%; Fig. 1). More broadly, these results show that integrating more datatypes in GEM improves diagnostic performance and results in greater algorithmic stability (Figs. 2 and 3).

About 70% (86/122) of the disease-causing variants in the benchmarking dataset are reported in ClinVar with pathogenic (P) or likely pathogenic (LP) clinical significance annotations. Moreover, each proband's whole-genome variant set contained on average 1.9 variants

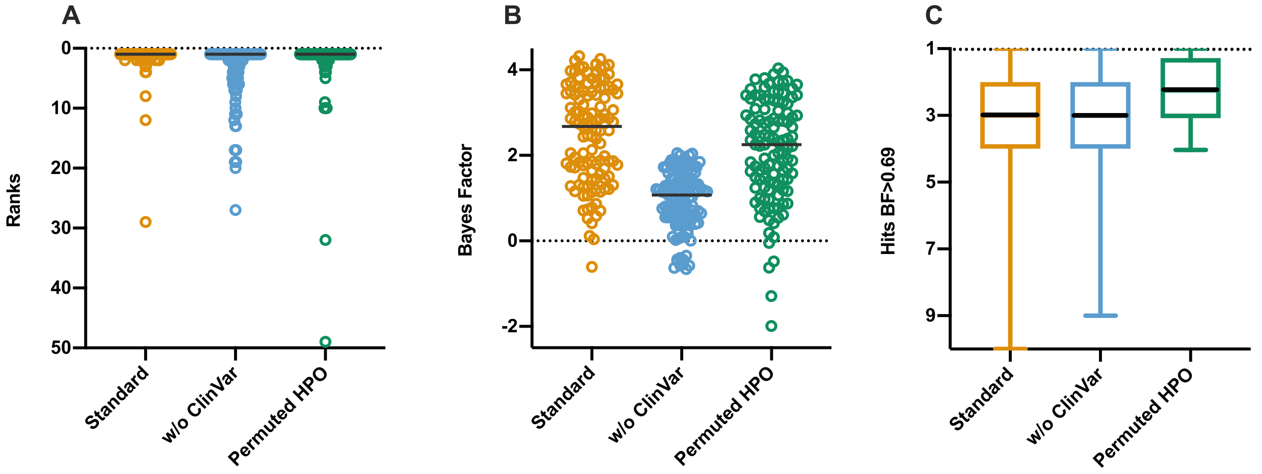

Fig. 3 Impact of missing data and mis-phenotyping on GEM performance in the benchmark cohort. Causal gene rank (**A**); Bayes factors for causal genes (**B**); and number of candidates (hits) above gene BF ≥ 0.69 threshold (moderate support) (**C**) under standard conditions, withdrawing ClinVar information, and permuting HPO terms extracted by CNLP. The black line in the graphs denotes the median

with ClinVar P/LP annotations. These two facts underscore the importance of ClinVar annotations for assisting diagnosis. They also make clear that tools that leverage ClinVar information need to avoid false positives which lead to longer candidate lists as non-causal genes also contain ClinVar P/LP variants. Additional file 1: Table S4 breaks down results for the benchmark cohort with respect to ClinVar annotations of causal variants. Overall, mean, and median ranks were slightly improved for diagnostic variants with ClinVar P/LP annotations *vs.* those without them (mean 1 *vs.* 3), with GEM showing the greatest improvement in ranks. Moreover, GEM maintained the same number of candidates with GEM gene score > 0 for both classes [10], demonstrating that GEM can use ClinVar status to improve diagnostic rates without increasing the number of candidates for review.

GEM performs equivalently on parent-offspring trios and single probands

Parent-offspring trios are widely used for molecular diagnosis of rare genetic disease. While a recent study showed that singleton proband sequencing returned a similar diagnostic yield as trios [91], interpretation of trio sequences is less labor-intensive. For example, trios enable facile identification of de novo variants, which is the leading mechanism of genetic disease in outbred populations [92]. Likewise, in recessive disorders, proband compound heterozygosity can be automatically distinguished from two variants in *cis*. However, these benefits are associated with increased sequencing costs. Moreover, both parents are not always available for sequencing or do not wish to have their genomes sequenced.

To understand how GEM performs in the absence of parental data, we reanalyzed the 63 trio and duo cases from the benchmark cohort as singleton proband cases. Surprisingly, we observed insignificant differences in the mean rank of the causal gene (Fig. 4A), GEM score of the causal gene (Fig. 4B), or number of candidates with BF ≥ 0.69 (Fig. 4C), using either manually or CNLP-extracted HPO terms. In contrast, this reanalysis was associated with a decline in the performance of Exomiser (Additional file 2: Figure S6). These analyses demonstrated that GEM was resilient to the absence of parental genotypes, a feature that could increase the cost effectiveness and adoption of WGS.

GEM scores optimize case review workflows

Conventional prioritization algorithms rank variants, enabling manual reviewers to start with the top ranked variants, and work their way down in the list until a convincing variant is identified for further curation, classification, and possible clinical reporting. This review process typically involves (a) assessing variant quality, deleteriousness, and prior clinical annotations; (b) evaluating whether there is a reasonable match between the phenotypes exhibited by the patient and those reported for condition(s) known to be associated with defects in the corresponding gene; and (c) considering the match in mode(s) of inheritance reported in the literature for the candidate disease and the patient's diplotype.

GEM accelerates this process, because it intrinsically considers variant quality, deleteriousness, prior clinical annotations, and mode of inheritance. Furthermore, at manual review, GEM gene scores summarize the relative strength of evidence supporting the hypothesis that the

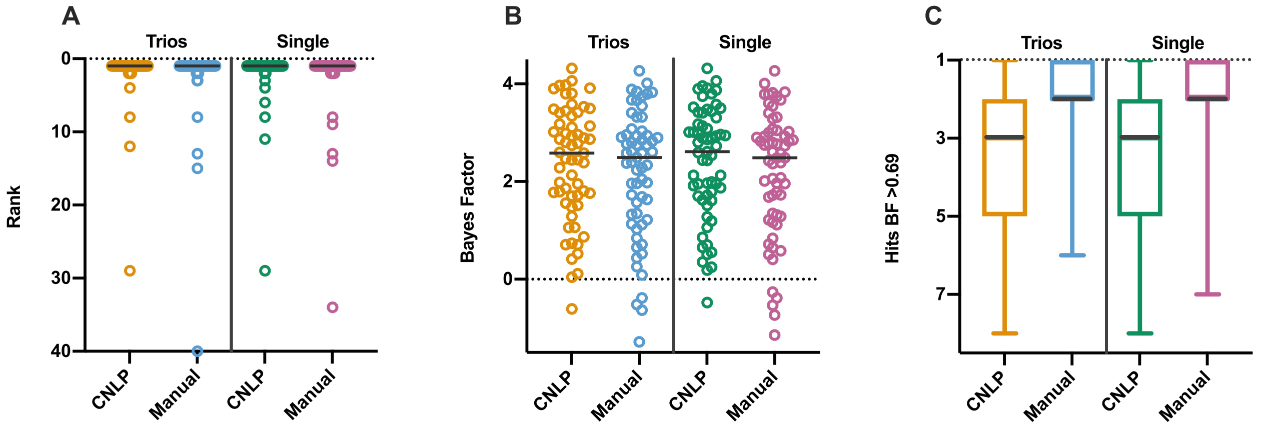

Fig. 4 Comparative performance of parent-offspring trios or duos vs. singleton probands in the benchmark cohort. Causal gene rank (**A**); Bayes factors (**B**); and number of candidates (hits) above gene BF ≥ 0.69 (moderate support) (**C**) for 63 cases analyzed as parent-offspring trios (*n* = 59) or duos (*n* = 4), as compared with analysis as single probands, using both manually curated or CNLP-derived HPO terms. The black line in the graphs denotes the median. No statistically significance difference between the any manual/CNLP groups was found between trios versus single probands using the two-tailed Wilcoxson matched pairs signed rank test

gene is damaged and that this explains the proband's phenotype.

GEM scores provide a logical framework for setting thresholds with regard to the optimal number of candidates that should be reviewed to achieve a desired diagnostic rate. This enables laboratory directors and clinicians to dynamically set optimal tradeoffs of interpretation time and diagnosis rate for specific patients, relative to their suspicion of a genetic etiology or results of other diagnostic tests.

We examined the effect of different BF thresholds on recall (true positive rate) and median number of gene candidates for review in the benchmark cohort (Fig. 5). In such analyses, it is germane to consider the concept of *maximal true positive rate (or recall)* to measure the theoretical proportion of true positive diagnoses recoverable by perfect interpretation when reviewing a set of *N* genes containing the true positive. For example, in the benchmark dataset, a GEM causal gene score threshold ≥ 0 would retain a median of ten candidates for review and provide a 99% maximal recall; whereas a threshold of ≥ 0.5 would retain a median of four candidates for review for a 97% maximal recall (Fig. 5).

These results illustrate how a tiered approach to case review using GEM gene scores could minimize the number of candidate genes to review, and, thereby manual interpretation effort. For example, a first pass review of candidates with a gene BF ≥ 0.69 provided an expected 95% diagnostic rate (and a corresponding median of 3 genes to be manually reviewed). If followed by a second pass using a threshold > 0, if no convincing candidates are found, an additional 4% possible diagnoses would be recovered, involving review of a median increment of seven genes. Application of this two-tiered approach to the benchmark dataset of 119 cases (Fig. 1), required manual final review of 395 candidate genes (3 genes in 115 cases and 10 genes in 5 cases), or an average of 3.3 candidate genes per case, for a maximal recall of 99%. Finally, review of candidates with BF < 0 recovered the last true positive in the benchmark cohort (*COL4A4*, ranked 40th in the GEM report with a BF = − 0.6. This case was a phenotypically and genotypically atypical autosomal dominant presentation of Alport syndrome 2 (MIM 203780).

Clinical decision support for diagnosis

Quantifying how well the observed phenotypes in a patient match the expected phenotypes of Mendelian conditions associated with a candidate gene is challenging for clinical reviewers and is a major interpretation bottleneck. In practice, clinicians look for patterns of phenotypes, biasing their observations. In addition, patient phenotypes evolve as their disease progresses. And there is considerable, disease-specific heterogeneity in the range of expected phenotypes. Simply comparing exact matches of the patient's observed HPO terms with those expected for that disease is suboptimal, because the observed and expected HPO terms are often hierarchical neighbors, rather than exact matches. Missing terms, particularly those considered pathognomonic for a condition, and "contradictory" terms further complicate such comparisons by clinicians. Thus, generation of quantitative, standardized, unbiased models of disease similarity has proven elusive.

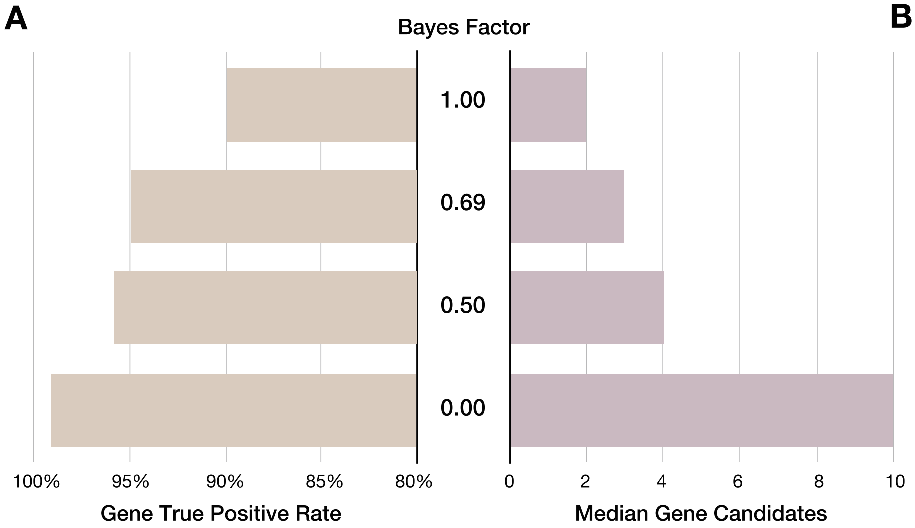

Fig. 5 Trade-off between GEM gene scores, maximal true positive rates, and number of candidates for review in the benchmark cohort. GEM gene scores are Bayes factors (BF) that can be used speed case review. **A** Gene maximal true positive rate achieved at the different BF thresholds (*Y*-axis). **B** Median number of candidate genes for review at each BF threshold. As the BF threshold is decreased, true positive rate increases, while the number of candidates to review remains manageable. Input HPO terms for this analysis were extracted by CNLP

GEM can automate or provide clinical decision support for this process via a condition match (CM) score ("Methods"). The GEM CM score summarizes the match between observed and expected HPO phenotypes for genetic diseases and considers the known mode(s) of inheritance, associated gene(s), their genome location(s), proband sex, the pathogenicity of observed diplotypes, and ClinVar annotations. Importantly, CM scores reflect relationships between phenotype terms as expressed in the HPO ontology graph, enabling inclusion of imprecise matches in similarity comparisons. CM scores can be used in a wide variety of clinical settings to prioritize and quickly assess possible Mendelian conditions as candidate diagnoses, a process we term *diagnostic nomination*.

Specific, definitive, genetic disease diagnosis remains a significant challenge for clinical reviewers, even with the short, highly informative candidate gene lists provided by tools such as GEM. This is because many genes are associated with more than one Mendelian disease. For example, application of a GEM causal gene score threshold ≥ 0.69 to the 119 probands in the benchmark cohort results in a median of 3 gene candidates per proband (c.f. Fig. 5), associated with a maximal gene recall of 95%. However, because many genes are associated with more than one disease, clinical reviewers would actually need to consider around 12 candidate Mendelian conditions per proband (data not shown). This difficulty is exacerbated by the fact that most laboratory directors are not physicians and lack formal training in clinical diagnosis.

Determination of a specific, definitive genetic disease diagnosis among several candidates can be accomplished with a combination of GEM CM scores and causal gene scores (Fig. 6). Using the benchmark cohort's true (reported) gene and disorder diagnoses as ground truth, we used a GEM gene score threshold ≥ 0.69 to recover gene candidates, and the associated CM scores to rank order the diseases associated with those gene candidates (Fig. 6A). Using CNLP-derived phenotypes, the true disease diagnosis was the top nomination by CM score in 75% of cases, within the top 5 in 91% of cases, and within the top 10 in 95% of cases. Performance was inferior with manually extracted phenotype terms. The area under the receiver-operator characteristic (ROC) curves (AUCs) were 0.90 and 0.88, for CNLP and manual terms, respectively (Fig. 6B). This implied that the larger number of CNLP-extracted terms conveyed greater information content, permitting better discrimination of the correct diagnostic condition, than sparse, manually extracted phenotypes [27].

In the benchmark cohort, 58 of the 100 candidate genes (excluding cases with causal, multigenic SVs) were associated with 2 or more disorders (median of 3 gene-disorder, maximum of 15; Additional file 2: Figure S7 shows the example of *ERCC6*). We measured how well the CM score distinguished between multiple, alternative disorders associated with the same gene (Fig. 6B). In these 58 cases, the AUC was less than that for CNLP with the entire set of candidate genes in the benchmark cohort (0.68 vs 0.9). This decrease can be at least partially explained by the high similarity (and in some cases identity) of the clinical features of different disorders associated with the same gene. Thus, a combination of GEM gene and CM scores can refine candidate disorders for clinical reporting, further reducing review times.

Reanalysis of previously unsolved cases

Recent reports show that reanalysis of older unsolved cases suspected of rare genetic disease can yield new

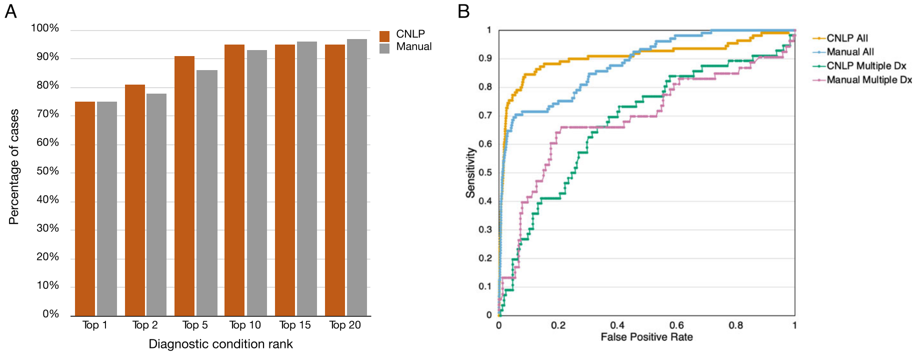

Fig. 6 Performance of GEM condition match scores for diagnostic nomination in the benchmark cohort. **A** Ranks for reported diagnostic conditions for the benchmark dataset, using a GEM gene BF score ≥ 0.69 and sorted by CM score, for HPO terms derived from CNLP or manual curation. **B** Receiver-operator characteristic curves for the condition match **(**CM) score for all hits with BF ≥ 0. CNLP All: HPO extracted from clinical notes by CNLP; AUC = 0.91. Manual: Manually curated HPO terms; AUC = 0.88. CNLP Multiple Dx: CNLP-derived CM score for the true positive disorder versus the other possible disorders associated with that gene; AUC = 0.68. Manual Multiple Dx: As for CNLP-derived CM but using manually curated HPO terms; AUC = 0.69

diagnoses supported by incremental increases in knowledge of pathogenic variants, disease-gene discoveries, and reports of phenotype expansion for known disorders [93, 94]. While worthwhile, there are barriers to reanalysis, such as limited reimbursement and low incremental diagnostic yield, that limit use to physician requests. Ideally, all unsolved cases would be reanalyzed automatically periodically, and a subset with high likelihood of new findings would be prioritized for manual review. The strong correlation between true positive rates and GEM gene scores (Fig. 5) suggested a strategy for triaging reanalyzed cases for manual review: only cases for which the recalculated GEM score had increased sufficiently to suggest a high probability of a new diagnosis would pass the threshold for manual review. Likewise, GEM condition match scores could be used to search all prior cases to identify the subset of unsolved cases with support for particular Mendelian conditions, aiding cohort assembly for targeted reanalysis based upon particular proband phenotypes, or for review by particular medical specialists. Of note, an advantage of CNLP is that it is possible to automatically generate a new clinical feature list at time of reanalysis. This is particularly important in disorders whose clinical features evolve with time and were the observed features may be nondescript at presentation.

To test the utility of GEM for reanalysis, we selected 14 unsolved cases that had rWGS performed by RCIGM. For these reanalyzes, we used CNLP-derived HPO terms (Table 3) and a more stringent gene BF threshold ≥ 1.5 to restrict the search to very strongly supported candidates. Ten cases yielded no hits. Four cases returned a total of 7 candidate genes. Review of three cases did not return new diagnoses. In the remaining case, a new likely diagnosis was made of autosomal dominant Shwachman-Diamond Syndrome (MIM: 260400) or severe congenital neutropenia (MIM: 618752) [95, 96], both of which are associated with pathogenic variants in *SRP54*. The respective CM scores using 261 CNLP-derived terms were relatively high (0.893 and 0.672, respectively). The association of *SRP54* and these disorders was first reported in November 2017 [95] and entered in OMIM in January 2020 [97], which explained why it was not identified as the diagnosis originally in July 2017. The identified candidate p.Gly108-Glu variant has been classified as “uncertain significance” by ACMG guidelines. However, if we were able to confirm de novo origin with paternal genotypes (which is currently lacking for this single proband case), the variant could be reclassified as “likely pathogenic” (meeting PM2, PM1, PP3, and PM6 of the ACMG guidelines). This was a singleton proband sequence and confirmation is being pursued. Thus, GEM reanalysis of 14 unsolved cases led to 7 gene-disorder reviews (an average of 0.5 per case), and yielded one likely new diagnosis, which was consistent with prior reanalysis yields [93, 94].

Conclusions

Here we described and benchmarked a Bayesian, AI-based gene prioritization tool for scalable diagnosis of rare genetic diseases by CNLP and WES or WGS. GEM improved upon prior, similar tools [19, 27, 28, 98, 99] by incorporating OMIM, HPO, and ClinVar knowledge explicitly, automatically controlling for confounding factors, such as sex and ancestry, compatibility with CNLP-derived phenotypes, SVs and singleton probands, and by directly nominating diplotypes and disorders, rather than just prioritizing variants.

In the cohorts examined, GEM had maximal recall of 99%, requiring review of an average of 3 candidate genes, and less than one half of the associated disorders nominated by other widely used variant prioritization methods per case. Improved diagnostic performance is anticipated to enable faster and more cost-effective, tiered reviews. GEM recall was essentially unaltered in the absence of parental genotypes in our data, meaning that full trio-sequencing is not always a requirement for high diagnostic yield. However, our cohort includes only definitively solved cases with 70% of variants already

Table 3 Previously undiagnosed cases with potential leads. Cases with hits with a GEM gene score BF > 1.5. *Zygo* zygosity, *Hom* homozygous, *Het* heterozygous, *Dup* large duplication

classified as P/LP in ClinVar; identification of less certain candidate variants and genes may still benefit from parental genotypes for ascertaining de novo variants, and for phasing alleles in genes associated to recessive conditions.

Uniquely, GEM provided AI-based unified gene prioritization for SVs and small variants. Hitherto, this has been frustrated by the high false positive rates of SV calls using short-read sequences and lack of a suitable framework for AI-based SV pathogenicity assertions [87, 88]. Furthermore, GEM inferred SV calls ab initio from WGS when they were not provided. These functionalities are critical for reanalyzing older cases, and for pipelines lacking SV calls.

Finally, in a small data set, we showed that GEM can efficiently reanalyze cases, potentially permitting cost-effective, scalable reanalysis of previously unsolved cases as disease, gene, and variant knowledge evolves [94, 100]. Indeed, integration of GEM and CNLP could enable automatic surveillance for rare disease patients [101] from genomes obtained for research or other clinical tests performed in healthcare [102, 103]. These combined features hold promise for reduced time-to-diagnosis and greater scalability for critical applications, such as in seriously ill children in the NICU/PICU [27, 104].

Acknowledgements

We thank Jeff Rule and Birgit Crain for help in extracting case data for the RCH cases from Fabric Enterprise, Brent Lutz for project management, and Sandy White for interinstitutional coordination (Fabric Genomics, Oakland CA). We are grateful to Joe Azure, Josh Grigonis, Jeff Rule, Bjoern Achilles-Stade, Peter Spiro, Gilberto De La Vega, Tara Friedrich (Fabric Genomics, Oakland, CA), Ray Drummond, Richard Littin, Aidan Scarlet, Mike Richdale, and Tim Dawson (NetValue Ltd, Hamilton, New Zealand) for software and architecture development efforts to implement GEM in the Fabric Enterprise platform. We also acknowledge Edward Kiruluta and Marco Falcioni (formerly Fabric Genomics) for useful discussions early on the project.

Authors' contributions

FV, MY, and SC designed the study and analysis strategy. MY developed the GEM algorithms. FV guided requirements, designed UIs, and led the software implementation. BM and EF implemented analysis pipelines. BM, EF, EJH, JM, FV, and MY performed data analysis. AF, AHB, BB, BSL, CAB, CAG, JM, KJ, KÕ, KR, LG, MH, MN NV, PBA, SC, SP, TW, and VN complied cases and clinical evidence. PB provided feedback on features and development. MGR and SK sponsored the project and provided helpful discussions and edits of the manuscript. FV and MY wrote the manuscript. All authors reviewed and suggested edits for the final version of the manuscript. The authors read and approved the final manuscript.

Funding

MH, KR, MN, and VN were supported in part by The Center for Rare Childhood Disorders, funded through donations made to the TGen Foundation. AF and BSL were supported by the DFG Cluster of Excellence "Precision Medicine in Chronic Inflammation". KO and SP were supported by Estonian Research Council grants PUT355, PRG471, MOBTP175, and PUTJD827. Sequencing and analysis were partially provided by the Broad Institute of MIT and Broad Center for Mendelian Genomics (Broad CMG) and was funded by the National Human Genome Research Institute, the National Eye Institute, and the National Heart, Lung and Blood Institute grant UM1 HG008900 and in part by National Human Genome Research Institute grant R01 HG009141. The phenotyping and analysis of patients at Boston Children's Hospital was funded by MDA602235 from the Muscular Dystrophy Association, and the Tommy Fuss Foundation, and the Yale Center for Mendelian Genomics. Sanger sequencing confirmations utilized the resources of the Boston Children's Hospital IDDRC Molecular Genetics Core Facility supported by U54HD090255 from the National Institutes of Health.

Availability of data and materials

The datasets supporting the conclusions of this article are included within the article and its additional files. Due to patient privacy, data sharing consent, and HIPAA regulations, our raw data cannot be submitted to publicly available databases. Anonymized outputs from GEM [70], Phevor [15], VAAST [14], and Exomiser [16] for the benchmark dataset cases are tabulated in Additional file 1: Tables S5-S8, and GEM for the validation data-set cases in Additional file 1: Table S10. Condition match scores for hits with gene BF > 0 used for Fig. 6 are tabulated in Additional file 1: Tables S11-S14. GEM, Phevor, and VAAST software implementations for versions used in this analysis are part of the Fabric Enterprise analysis platform and are commercially available [70]. Exomiser source code (version 12.1.0) is available on GitHub [105].

Declarations

Ethics approval and consent to participate

The need for Institutional Review Board Approval at Rady Children's Hospital for the current study was waived as all data used from this project had previously been generated as part of IRB approved studies and none of the results reported in this manuscript can be used to identify individual patients. The studies from which cases derived from were previously approved by the Institutional Review Boards of Rady Children's Hospital, Boston Children's Hospital (IRB protocols 03-08-128R and 10-02-0053), Christian-Albrechts University of Kiel (approval #A-156/02), HudsonAlpha Institute for Biotechnology (Western Institutional Review Board #20130675 and the University of Alabama at Birmingham #X130201001), the Translational Genomics Research Institute (WIRB® Protocol #20120789), and the Research Ethics Committee of the University of Tartu (approvals #263/M-16 and #2871N). These studies were performed in accordance with the Declaration of Helsinki and informed consent was obtained from at least one parent or guardian.

Genomics of asthma, allergy and chronic rhinosinusitis: novel concepts and relevance in airway mucosa

Anu Laulajainen-Hongisto[1,2†], Annina Lyly[1,3*†], Tanzeela Hanif[4], Kishor Dhaygude[4], Matti Kankainen[5,6,7], Risto Renkonen[4,5], Kati Donner[6], Pirkko Mattila[4,6], Tuomas Jartti[8], Jean Bousquet[9,10,11], Paula Kauppi[3†] and Sanna Toppila-Salmi[3,4†]

Abstract

Genome wide association studies (GWASs) have revealed several airway disease-associated risk loci. Their role in the onset of asthma, allergic rhinitis (AR) or chronic rhinosinusitis (CRS), however, is not yet fully understood. The aim of this review is to evaluate the airway relevance of loci and genes identified in GWAS studies. GWASs were searched from databases, and a list of loci associating significantly ($p < 10^{-8}$) with asthma, AR and CRS was created. This yielded a total of 267 significantly asthma/AR–associated loci from 31 GWASs. No significant CRS -associated loci were found in this search. A total of 170 protein coding genes were connected to these loci. Of these, 76/170 (44%) showed bronchial epithelial protein expression in stained microscopic figures of Human Protein Atlas (HPA), and 61/170 (36%) had a literature report of having airway epithelial function. Gene ontology (GO) and Kyoto Encyclopedia of Genes and Genomes (KEGG) annotation analyses were performed, and 19 functional protein categories were found as significantly ($p < 0.05$) enriched among these genes. These were related to cytokine production, cell activation and adaptive immune response, and all were strongly connected in network analysis. We also identified 15 protein pathways that were significantly ($p < 0.05$) enriched in these genes, related to T-helper cell differentiation, virus infection, JAK-STAT signaling pathway, and asthma. A third of GWAS-level risk loci genes of asthma or AR seemed to have airway epithelial functions according to our database and literature searches. In addition, many of the risk loci genes were immunity related. Some risk loci genes also related to metabolism, neuro-musculoskeletal or other functions. Functions overlapped and formed a strong network in our pathway analyses and are worth future studies of biomarker and therapeutics.

Keywords: Asthma, Allergic rhinitis, Airway epithelium, GWAS, Gene ontology, Pathway

Background

Asthma, allergic rhinitis (AR) and chronic rhinosinusitis (CRS) are multifactorial chronic airway diseases that share some common pathogenetic mechanisms. AR is caused by allergen binding to specific IgE in the nasal mucosa of a sensitized individual, leading to inflammation and symptoms of allergy. The prevalence of AR has increased in the Western countries over the last few decades and it nowadays has been estimated to affect up to 10–25% of the population [1]. Asthma is a chronic pulmonary disease with airway inflammation, bronchial hyperresponsiveness and recurrent, reversible airflow obstruction. Exacerbations are common both in asthma and in CRS, which is a chronic symptomatic inflammation of the sinonasal tract. Asthma and CRS both affect

about 3–10% of the Western population [2–4]. Risk factors for asthma, AR and CRS include genetic predisposition, other allergic diseases, infections and environmental factors including exposure to tobacco smoke and air pollution [5–7].

Many of the environmental risk factors in the pathogenesis of asthma and CRS are linked to disrupted interplay between epithelial barriers, particles, allergens and microbes [8, 9]. Type 2 biased inflammation with recruitment of eosinophils, basophils, and T-cells, and release of cytokines is common in atopic asthma and AR [10, 11]. Epithelial cells are in contact with microbes, which increasingly have been shown to have a role in inflammatory diseases [12, 13]. Recent studies have also found that altered airway microbiome composition might be associated with asthma [14], seasonal AR [15–17], or children with rhinitis [18].

Genetic inheritance has been estimated to explain 25–80% of asthma risk [19] and up to 90% of AR risk [20]. The genetic predisposition of CRS seems to vary according to CRS type. Although an increased risk is associated with both types, the familial risk of CRS with nasal polyps (CRSwNP) has been found significantly higher than that of CRS without nasal polyps (CRSsNP) in a population based study conducted in Utah [21].

Large collaborative twin studies and GWAS projects have helped establishing genetic components for asthma, CRS and AR. Kim et al. [22] summarized the results of 42 GWASs of asthmatic subjects and controls and asthma-related traits. The most replicated loci with genome-wide significant ($p < 5 \times 10^{-8}$) were the cluster of genes at the 17q12–21, including *ORMDL3* (orosomucoid-like 3), *GSDMB* (gasdermin B), and *GSDMA* (gasdermin A), specific to childhood-onset disease. The next three loci achieving significant p-values included loci 2q12 in the vicinity of several interleukin receptor genes, namely *IL1RL1, IL1RL2*, and *IL18R1*, a region on 5q22 that contains the mitochondrial solute carrier gene *SLC25A46* and the hemopoietic cytokine gene *TSLP* and a complex region located within the major histocompatibility locus 6p21. While these multigene loci are challenging to dissect, it is notable that *IL1RL1* encodes the receptor for IL-33. The gene that encodes IL-33 is separately implicated in the genetic etiology of asthma through the fifth most replicated locus on chromosome 9p24.

Like many other complex diseases, the development of asthma or AR requires genetic predisposition and appropriate timing of environmental exposures. GWASs have been able to identify and replicate several significant risk regions in large sample sets [10]. Among already known important asthma loci, GWASs have also revealed previously undescribed and unexpected genetic components, highlighting the method's freedom of preconceptions [23].

Risk factors and pathogenetic mechanisms of allergic diseases are also interrelated and share partly same mechanisms, which is why we took this broad approach. Our aim was to review GWASs identified asthma, AR and CRS related genes, and to evaluate their relevance in airway mucosal functions. This review is based on an extensive literature search, and several database searches (Fig. 1).

GWAS catalog-search

The GWAS catalog containing 11,598 unique SNPs, was downloaded from the National Human Genome Research Institute (NHGRI) website (https://www.ebi.ac.uk/gwas/) on January 18, 2018. We created a list of 267 SNPs associating significantly (p < 10 exp -8) with asthma and/or AR provided in the Additional file 1: Table S1. There were no SNPs associating significantly with CRS. Gene symbols were mapped onto chromosomes by using Ensemble Karyotype viewer (https://www.ensembl.org/Homo_sapiens/Location/Genome) (Additional file 1: Table S1). Of these 267 SNPs, we selected the SNPs which were assigned to a protein coding gene or those reported to have a protein coding gene as the nearest gene [24]. Using this strategy, we identified a total of 170 protein coding genes (Additional file 1: Table S2). Of them, 21 genes were connected to several SNPs and/or identified in different studies. A Manhattan plot (https://biorender.com/) of SNPs was generated (Fig. 2), showing that susceptibility genes were distributed to all chromosomes (except sex chromosomes). Several genes were found to locate in chromosomes 1, 5, 6, or 17.

Database and literature search of airway expression of the protein expressing genes

Information about the 170 protein coding genes in Gene Cards, NCBI Gene Expression Omnibus (GEOaccession: GSE5057 and GSE40364), and Human Protein Atlas (HPA) (https://www.proteinatlas.org/) was examined (Fig. 3). We also collected lung, bronchial, and nasopharyngeal expressions of these genes from the Genotype tissue expression portal (GTEx), expressed as Reads Per Kilobase Million (RPKM) (Additional file 1: Table S2).

Nasopharyngeal/bronchial protein expression information was obtained from immunohistochemically stained photomicrographs of HPA, and the staining intensity was semiquantitatively scored as 0–3 (0 = no, 1 = mild, 2 = moderate, 3 = strong staining). A total of 76/170 (44%) of these genes showed bronchial epithelial protein expression and 69/170 (41%) showed nasopharyngeal epithelial protein expression in stained microscopic figures

19 GO categories 15 KEGG pathways associated with the genes at p<0.05 level
54 genes highly suggestive for airway functions are further described in the Results –chapters: Epithelial function, Immunity function, Neuro-musculoskeletal function and Other function

Fig. 1 Flow chart of the study. GWASs were searched from databases (https://www.ebi.ac.uk/gwas/) and a list and database of SNPs associating significantly ($p < 10^{-8}$) with asthma, AR and CRS was formed in 1/2018. Gene Ontology (GO) and Kyoto Encyclopedia of Genes and Genomes (KEGG) annotation analysis was performed for protein coding genes connected to SNPs. Airway epithelial expression of genes and corresponding proteins were evaluated by using Gene Cards, Human Protein Atlas (HPA), and literature search from PubMed. Other potential airway functions of the selected set of genes were evaluated from database /literature search. Abbreviations: *AR* allergic rhinitis, *CRS* chronic rhinosinusitis, *GO* Gene Ontology, *GWAS* genome-wide association study, *HPA* Human Protein Atlas, *KEGG* Kyoto Encyclopedia of Genes and Genomes, *SNP* single nucleotide polymorphism, *TPM* Transcripts Per Million

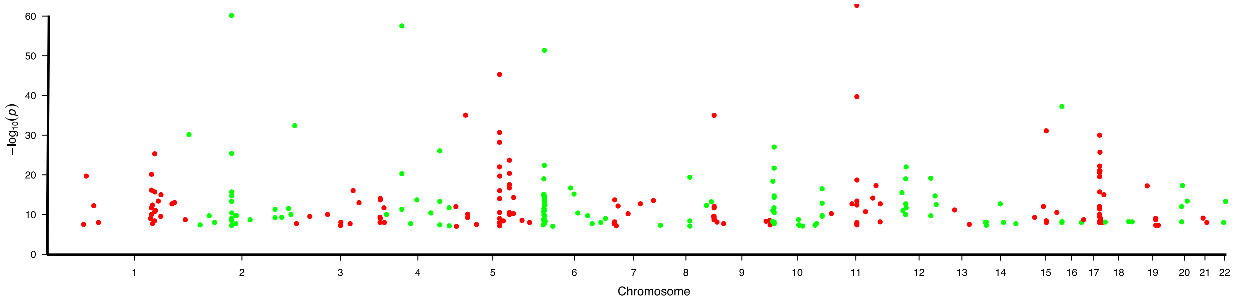

Fig. 2 Manhattan plot (https://biorender.com/) of the SNPs that were significantly associated (p < 5 × 10–8) with asthma/AR in GWASs

(Fig. 3a). The proportion of genes that did not have protein expression figures available was 55% in bronchial and 59% in nasopharyngeal region (Fig. 3a). All available stained microscopic figures showed airway expression, and when scoring semiquantitatively the staining intensity, the proportion of genes showing moderate protein

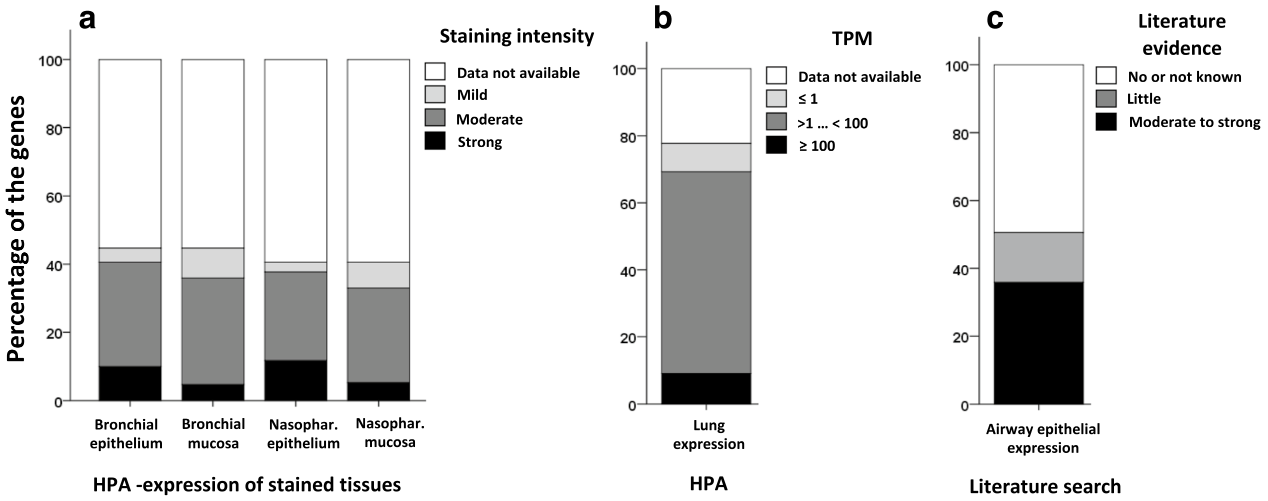

Fig. 3 Database and literature analysis of airway expression of the corresponding proteins of the protein coding GWAS-level genes (n = 170) associating with asthma/AR. **a** Human protein Atlas (HPA) was used to search for photomicrographs of the proteins and their staining intensity was semi-quantitatively evaluated by two observers. **b** HPA results of lung expression in Transcripts per million (TPM). **c** Literature search results of airway epithelial expression of these genes. Pubmed search was performed by using search terms "(Gene name OR alias) AND epitheli* AND airway/bronc*", Nasophar = Nasopharyngeal

expression intensity of all available figures was 68% in bronchial and 64% in nasopharyngeal regions (Fig. 3a). Similarly, the proportion of genes with overall expression was 45% in bronchial and 41% in nasopharyngeal mucosa (Fig. 3a). When evaluating the normalized expression values, e.g. transcripts per million (TPM) in HPA, 51/170 (30%) genes did not show data, 106/170 (62%) genes showed TPM > 1 and 8% genes showed TPM value of < 1 (Fig. 3b). The exact TPM values are shown in the Additional files 1, 2: Tables S1 and S2. When evaluating Genotype-Tissue Expression (GTEx) from HPA, the expression levels for the vast majority of these genes were not available (Additional files 1, 2: Tables S1 and S2).

A systematic literature search in PubMed was performed for the 170 protein coding genes, by using as search terms "Gene name (or any of its aliases) AND epitheli* AND airway/bronc*" and information of airway epithelial expression was scored as 0–2 (0 = no evidence of airway expression, 1 = maybe, 2 = yes/ubiquitous expression) (Additional files 1, 2: Tables S1–S2). A total of 25/170 (15%) genes showed little and 61/170 (36%) showed moderate to strong evidence of airway epithelial protein expression, whereas 49% of genes showed no/not known evidence of airway epithelial protein expression (Fig. 3c).

Functional annotation

We performed functional annotation of the identified genes by R, using a package called clusterProfiler (https://bioconductor.org/packages/release/bioc/html/clusterProfiler.html) (Fig. 4) [25]. The SNPs (Additional file 1: Table S1) that were connected to the protein coding genes were used. If several SNPs were in/near to the same gene, only the first SNP of the list of the Additional file 1: Table S1 was used in functional annotation. Noncoding genes related to these asthma/AR -associated SNPs were excluded in functional annotation. Altogether, there was a total of 155 genes showing functional annotation (Fig. 4). We identified 19 Gene ontology (GO) categories (functional protein categories) that were significantly ($p < 0.05$) enriched among these genes, such as cytokine production, cell activation, leukocyte differentiation, regulation of cell adhesion, leukocyte proliferation, adaptive immune response, antigen receptor signaling pathway and regulation of inflammation response (Fig. 4a). Gene network analysis showed strong interaction between these GO-categories, indicating a strong regulation network between the genes (Fig. 4b). We also identified 15 Kyoto Encyclopedia of Genes and Genomes (KEGG) pathways that were significantly ($p < 0.05$) enriched among the genes, such as Th17 cell differentiation, Th1 and Th2 cell differentiation, Human T-cell leukemia virus 1 infection, Inflammatory bowel disease, Epstein Barr virus infection, Tuberculosis, Hematopoietic cell lineage, JAK-STAT signaling pathway, and asthma (Fig. 4c). JAK-STAT signaling pathway was the most significantly enriched pathway (Fig. 4c).

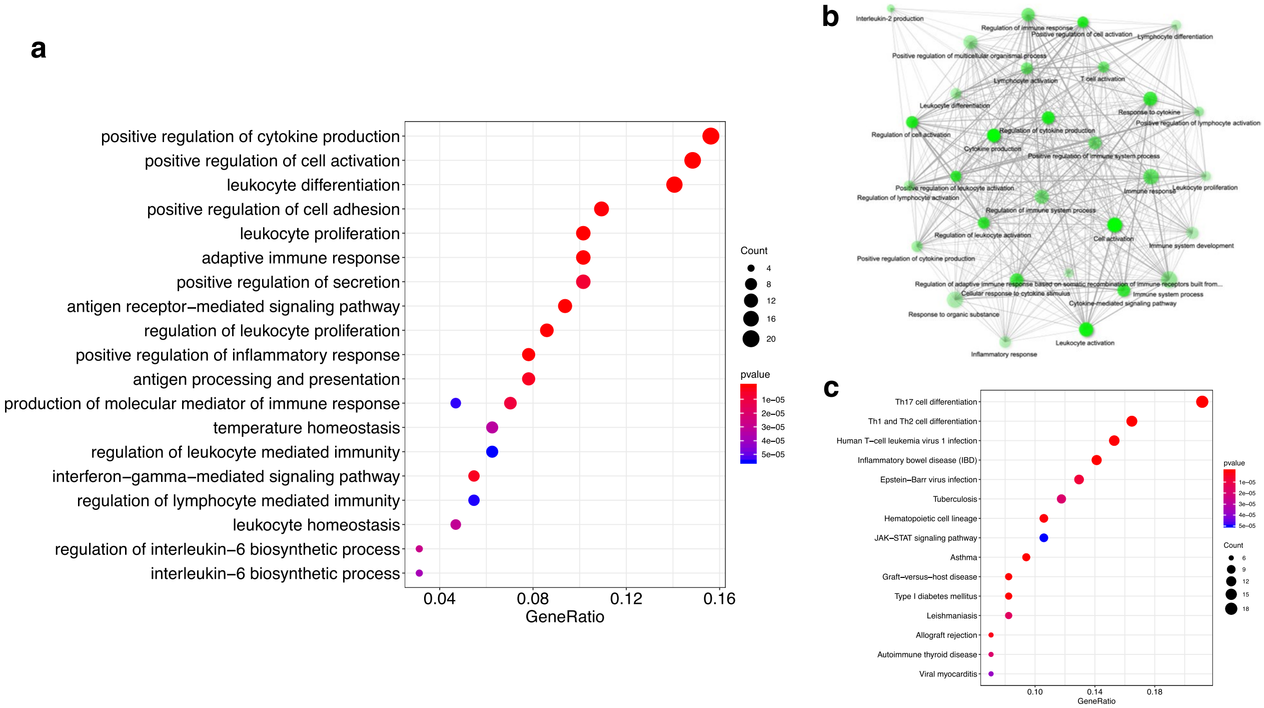

Fig. 4 Functional annotation of the genes corresponding to the SNPs that were significantly associated with asthma/AR in GWASs. We used the whole list of SNPs (Ensemble codes) shown in the Additional file 1: Table S1. Of these, only SNPs that were connected to protein coding genes were used in this analysis, and only one unique gene associated with one or several SNPs were used. Noncoding genes related to these asthma/AR -associated SNPs were excluded in functional annotation. The total number of genes of this functional annotation was 155 genes. **a** Gene ontology (GO) categories (functional protein categories) that were enriched. **b** Gene function network interaction of the GO-categories. The network interaction shows strong interaction between the GO-categories and indicating regulation functions between each other. **c** Kyoto Encyclopedia of Genes and Genomes (KEGG) pathways enriched among 155 genes. Shades of blue and red indicate significance of the enrichment (all were significant at level $p < 0.05$), and the size of the dot represents gene count. X-axis represents the number of genes belonging to the particular category / total number of observed genes ($N = 155$)

Literature review

We finally ranked genes that were highly suggestive of having asthma/AR-relevant functions. The selection was performed based on (a.) the significance (p-value) of particular SNP in GWASs, or (b.) multiple replication of particular SNP or gene in GWASs, or (c.) large literature knowledge of airway function of a particular gene (Additional file 1: Table S1). The selected list of genes is shown in bold text in Table 1. We searched expression knowledge from literature for this smaller set of genes and categorized the genes based on their potential function in the airways in four main groups: genes related to epithelial function, immunity function, neuro-musculoskeletal functions, and other functions. Although some functional groups overlap, genes are only reported in one functional group. In the following text we will discuss the most relevant genes we found in these searches. In Fig. 5 we summarize the main airway functions related to the genes we evaluated most relevant for functions in nasal mucosa during AR and in bronchial mucosa during asthma.

Epithelial function—related genes

CHI3L1 (Chitinase-3-like protein 1) gene encodes chitinase like protein (YKL-40), which is involved in inflammation and tissue remodeling [26]. A study combining GWAS with serum YKL-40 measurement, involving 632 members of the Hutterite population of European decent (living in South Dakota) (age range 6–92 years; asthma in 11.5%, atopy in 41.2%), have shown *CHI3L1* (SNP rs4950928, -131C->G) to be a susceptibility gene for asthma, bronchial hyperresponsiveness, and reduced lung function [27]. Elevated circulating YKL-40 levels have been shown to be a biomarker for asthma [27, 28], they have been shown to correlate with asthma severity,

thickening of subepithelial basement membrane, and inversely with lung function [26].

CDHR3 (Cadherin related family member 3) gene is a transmembrane protein with six extracellular cadherin domains [29]. Cadherins are highly expressed in airway epithelium, and are involved in cell adhesion, epithelial polarity, cell–cell interactions and differentiation [29]. *CDHR3* is expressed in FOXJ1-expressing ciliated cells, which are also the targets of Rhinovirus C (RV-C) binding [30]. GWAS was performed for blood samples of 1173 Danish children (2–6 years) with recurrent acute hospitalizations for asthma, and *CDHR3* (SNP rs6967330; p.Cys529Tyr) has been identified as a susceptibility gene for early childhood asthma with severe exacerbations [29, 31]. Since asthma exacerbations are often caused by infections, it is possible that *CDHR3* variations increase susceptibility to infections, and exacerbations, because of disrupted epithelial integrity [31].

Chromosome 17q21 is an area of interest for asthma and contains a cluster of genes linked to asthma in several GWAS studies, including the *GSDMB* (Gasdermin B) and *IKZF3* (Ikaros family zinc finger protein 3) genes [32]. Chromosome 17q21 has also been linked to inflammatory bowel disease, primary biliary chirrosis, and type 1 diabetes mellitus [32, 33].

Gasdermin A (GSDMA) and B (GDSMB) belong to a family of pore-forming proteins, causing membrane permeabilization and pyroptosis, which is a lytic pro-inflammatory cell death type [34]. Gasdermins are involved in inflammation and cell death, in several herediatry diseases, auto-inflammatory diseases and cancer [34]. *GSDMB* is highly expressed in ciliated airway epithelial cells [35]. Associations have been shown between *GSDMA* gene and asthma [36, 37] and, between *GSDMB* gene and asthma [38] or early childhood asthma with severe exacerbations [39]. Moffat et al. 2010 found an independent association with childhood-onset asthma and *GSDMA* gene (rs3894194, G-> A) in their large consortium-based GWAS of asthma in children and adults from several different populations [36]. Ferreira et al. 2014 found in their GWAS meta-analysis including children and adults from different populations, that *GSDMA* gene (rs7212938, G) was associated with risk of asthma without hay fever (OR 1.14, 95% CI 1.07–1.22) and less

with risk of hay fever without asthma (OR 1.02, 95% CI 0.98–1.06), suggesting that it is a stronger risk factor for asthma than hay fever [37].

The *GSDMB* gene (rs11078927, C->T) has been linked with asthma by Torgerson et al. 2011, in a GWAS meta-analysis including children and adults from different populations [38]. Also Bønnelykke et al. 2014, linked *GSDMB* gene (rs2305480, G) with early childhood asthma with severe exacerbations in their GWAS of Danish children [39].

A large GWAS of European 180,129 adults/children with asthma and/or AR and/or eczema and 180,709 healthy controls showed that *GSDMB* gene (rs921650 A) is a stronger risk factor for asthma or hay fever than for eczema [40]. A meta-analysis of GWASs of self-reported pollen, dust-mite or cat allergy of 22 012 allergic subjects and 31 850 healthy controls showed that *GSDMB* gene (rs9303280, T->C) was most strongly associated with asthma [41]. A meta-analysis of GWAS of 2144 asthmatic Puerto Ricans and 2893 healthy controls (adults & children) found *GSDMB* gene (rs2305480, G—>A and rs11078927, C—>T) to be associated with asthma [42]. *GSDMB* was highly expressed in nasal epithelial brushings of Puerto Rican children [43], and in primary bronchial epithelium of asthmatic lung [44]. A Dutch GWAS included 920 physician diagnosed asthmatic subjects with bronchial hyperresponsiveness and 980 healthy controls, from northern Netherlands, both children and adults. They compared the GWAS results to prior GWASs, and also performed lung tissue eQTL analysis of the top SNPs replicated in the GWAS analysis [45]. The 17q21 locus achieved genomewide significance, with *GSDMB* (rs8067378, G; rs2305480, A; rs2290400, C; rs7216389, C), also in eQTL analysis, *GSDMB* showed larger effect sizes compared to prior published literature [45]. Exactly how gasdermins affect asthma risk remains unknown, membrane permeabilization and pyroptosis may have an effect in this [35]. When GSDMB protein is cleaved by inflammatory caspase-1 to release its N-terminal fragment, potent pyroptotic cell death had been shown to be induced in airway epithelial cells [35]. There is some evidence that a *GSDMB* splice variant, associated with lower asthma risk, causes an exon deletion leading to GSDMB protein losing its ability to induce pyroptosis in airway epithelial cells, possibly reducing asthma risk [35].

Ikaros family zinc finger protein 3 (IKZF3)s are transcriptional factors involved in lymphocyte differentiation [46] and are expressed in human airway epithelial cells [47]. In a GWAS of Dutch asthmatics with bronchial hyperresponsiveness, *IKZF3* (rs9303277, T) was one of the top findings, and also significant in the lung tissue eQTL analysis [45]. In the meta-analysis of GWAS of asthma in Puerto Ricans (children and adults), the only locus that achieved genome-wide significance for asthma risk was *IKZF3*, (rs907092) at chromosome 17q21 [42]. *IKZF3´*s role in asthma pathogenesis is unknown.

Zinc finger proteins are involved in many cellular processes, and in the development and differentiation of several tissues [48–50]. They are involved in tumorigenesis, cancer progression and metastasis formation e.g. in breast cancer, but can also act as tumor suppressor genes, and are also involved in neurodegeneration, skin diseases (e.g. psoriasis) and diabetes mellitus [48–50]. In the large GWAS of broad allergic disease phenotype (asthma and/or hay fever and/or eczema) by Ferreira et al. [20], *ZNF217* (Zinc Finger Protein 217) gene was one of the identified loci containing genetic risk variants independently associated with the risk of allergic disease [40]. In a GWAS study of Caucasian asthmatic children of which 172 were treated with budesonide and 409 with placebo or nedocromil, the *ZNF432* gene (rs3752120, T—>C) variants were associated with inhaled corticosteroids modulating bronchodilatator response, also *ZNF614* (rs2288884, rs3450) and *ZNF841* (rs12460587, G->T, rs3450) were closely associated [51].

Filaggrin (FLG) is a protein that is critical for keratinization and epithelial barrier homeostasis [52]. Filaggrin gene defects are known to increase the risk of allergic sensitization, atopic eczema and AR [53]. It is the most important genetic risk factor for atopic dermatitis [52, 54]. A GWAS of 1563 European children with physician diagnosed asthma and 4054 controls and a replication analysis showed that, the risk for asthma caused by *FLG* variants (R501X and 2282del4) is limited to asthma cases with co-existing atopic dermatitis [55]. *OVOL1* gene encodes a putative zinc finger containing transcription factor that is highly similar to homologous protein in Drosophila and mouse. *OVOL1* regulates FLG expression in atopic dermatitis subjects [56], and in normal human epidermal keratinocytes [57]. It has been suggested that *FLG* mutations might be involved in barrier dysfunction leading to e.g. asthma. However, in immunohistochemical analysis, filaggrin was not found to be expressed in normal upper airway epithelium in a disagreement with this theory [58].

Toll-like receptors (TLRs) are expressed in nasal epithelium [59], and they have an important innate immunity function recognizing external pathogens and activating immune responses [41]. Nasal epithelial *TLR* gene expression levels were not remarkably altered after nasal birch pollen challenge [59] although a decrease in nasal epithelial TLR1 and TLR6 protein expression was detected in birch pollen allergic adults after challenge [59]. In the meta-analysis of GWASs that have been performed on both children and adult populations with self-reported allergy, the found shared susceptibility loci with asthma included (rs2101521, A->G) chromosome 4p14 near *TLR1*, *TLR6* and *TLR10* [41]. In the meta-analysis of GWASs of children and adults with asthma and hay fever, and controls, *TLR1* (rs4833095, T) was associated with the risk of asthma with co-existing hay fever [37]. The *TLR1* gene was also found to be one of the identified loci containing genetic risk variants independently associated with the risk of allergic disease in the large GWAS of broad allergic disease phenotype (asthma and/or hay fever and/or eczema) by Ferreira et al. [40].

SMAD family member 3 (*SMAD3*) is a transcriptional modulator activated by TGFβ and it may regulate homeostatic and healing pathways to epithelial damage [36]. Mice with SMAD3 deficiency have increased amounts of proinflammatory cytokines in their lungs [60]. The GWAS by Moffat et al. showed an independent association between asthma and the *SMAD3* SNP (rs744910, G->A) [36]. In two GWAS meta-analyses, *SMAD3* SNP (rs17228058, A->G) was a susceptibility locus of asthma and self-reported allergy [41] and, asthma with co-existing hay fever, but not asthma alone [37].

The role of epithelial to mesenchymal transition (EMT) has a critical role in airway remodeling. Human eosinophils co-cultured with bronchial epithelial cells induced EMT, suggestive of their role in airway remodeling, with increased expression of TGFβ1 and *SMAD3* phosphorylation in the bronchial epithelial cells [61].

ITGB8 gene encodes Integrin Subunit Beta 8. This protein noncovalently binds to an alpha subunit to form a heterodimeric integrin complex. In general, integrin complexes mediate cell–cell and cell-extracellular matrix interactions and this complex plays a role in human airway epithelial proliferation. High expression levels of

ITGB8 have been associated with high angiogenic and poorly invasive glioblastoma tumors. Inactivation of *ITGB8* in the murine airway has been associated with a reduction in IL-1β–induced airway inflammation and fibrosis, which is due to decreased TGF-β activation [62].

Immunity function–related genes

Immunity related SNPs in asthma are mostly in genes linked to HLA region and type 2 inflammation. The region 6p21 (*HLA* region) is one of the most replicated asthma loci [22]. Several significant SNPs have been associated with class II major histocompatibility antigen (*HLA-DR*) genes including *HLA-DQA1*, *HLA-DQA2* and *HLA-DQB1* [38]. They play a central role in the immune system by presenting peptides derived from extracellular proteins. Class II molecules are expressed in antigen presenting cells, ie. B lymphocytes, dendritic cells and macrophages and are extensively studied because of the association with several autoimmune, infectious and inflammatory diseases [63].

Group-specific Component (*GC*) gene [also known as Vitamin D-binding protein (*VDBP*) gene] on chromosome 4q13 and has been found to associate with asthma in children [64]. The rs7041 G-allele was found with increased risk [OR 2.15, CI 95% (1.32–3.50; $P = 0.002$)] of asthma in codominant, dominant, recessive and allelic models [64]. VDBP carries circulating vitamin D to the target organs, it is a chemotactic factor for leukocytes and macrophage activation, and also has a role in osteoclast activation [64, 65].

Approximately half of the patients with asthma, regardless of the severity of the disease, exhibit type 2 endotype. The endotype is characterized by a predominant activation of Th2 cells that produce cytokines such as interleukins 4, 5, and 13. These interleukins are responsible of Th2 cell differentiation, maturation and release of eosinophils and proliferation of IgE-producing B-cells, respectively [66]. IL-25, IL-33 and TSLP are thought to be master regulators of type 2 inflammation in diseases and they can all activate innate and adaptive immune cells to secrete IL-5 and IL-13 [67].

Interleukin 1 receptor like 1 (*IL1RL1, ST2*) is an important asthma gene and part of a cytokine receptor gene cluster. GWASs have reproducibly found the *IL1RL1* gene to be associated with asthma susceptibility [22]. *IL1RL1* encodes different isoforms of the receptor: IL1RL1-a is a soluble form and IL1RL1-b is a transmembrane receptor. IL1RL1-a functions as a decoy receptor to dampen IL-33 induced signaling. IL1RL1-b together with IL1RAcP forms a heterodimeric transmembrane receptor for its ligand, IL-33. Binding of IL-33 initiates an MyD-88-mediated signaling cascade, releasing pro-inflammatory cytokines IL-4, IL-5 and IL-13 [68]. *IL-33-ST2* (*IL-1RL1*) axis has been regarded as one of the key players also in allergic diseases, asthma and atopic dermatitis [69]. A number of studies have indicated that IL-33 induces the activation and expansion of group 2 innate lymphoid cells (ILC2s) which cause allergic inflammation by producing large amounts of IL-5 and IL-13 [70]. As IL-5 is the main component of eosinophil activation and survival, anti-IL-5 treatments are used to inhibit eosinophilic inflammation. At the moment, three biologics targeting IL-5 signaling are available: mepolizumab and reslizumab, which bind to IL-5 directly reducing the production and survival of eosinophils, and benralizumab, which targets the IL-5 receptor expressed on eosinophils causing a direct destruction of the cell type [71]. Many functional studies of asthma have focused on peripheral blood mononuclear cells, yet there are also some studies on granulocyte functions: a study has showed that persistent high blood neutrophilia was associated with poor asthma control [72].

Region 9p24 also belongs to one of the most replicated asthma loci, associating with the *IL-33* gene. Being one of the major upstream regulators of type 2 inflammation, *IL-33* has been linked to both asthma and allergic inflammation. It also functions as an”alarmin” and is secreted following tissue damage caused for example by an infection [68]. *IL-33* expression in the lungs is increased in asthma [73]. A recent publication describes a rare loss-of-function mutation in *IL-33,* protecting from asthma [74]. Recently, a biologic recombinant protein called IL-33trap was shown to neutralize IL-33 and inhibit acute allergic airway inflammation in a mouse model [75]. Clinical trials are ongoing with several monoclonal antibodies targeting *IL-33/ST2* signaling [76].

IL-13 is a cytokine secreted by activated Th2 cells, and acts as an important mediator of allergic inflammation pathogenesis. It shares a common receptor subunit with IL-4, namely IL-4Ralpha, therefore sharing also many functions with it, including promoting B-cell proliferation and class switch to IgG4 and IgE [77]. Dupilumab, a biologic targeting this common receptor subunit, has been shown to be effective in many allergic diseases including asthma, atopic dermatitis [78] and CRSwNP [79]. Some functions of IL-13 are independent of IL-4, and especially mucus hypersecretion, subepithelial fibrosis and stimulation of matrix metalloproteinases resulting in emphysematous changes in mouse model has been shown to result from the functions of IL-13 [80, 81]. A recent study investigated the association of 236 candidate gene polymorphisms and asthma disease severity, and found only one marker, the rs848 in the *IL-13* gene region, significantly associating with symptom severity in adults with asthma [82].

TSLP (thymic stromal lymphopoietin) gene encodes a cytokine that is expressed mainly in epithelial cells and plays a key role in allergic inflammatory responses [83]. In humans, dendritic cells are the major target for TSLP, having an integral role on promoting Th2 cell responses. TLSP is produced by the airway epithelium in response to inhaled allergens and proinflammatory stressors and has an upstream role in the asthma cascade [83]. Tezepelumab binds to TSLP, inhibiting its stimulating activity on dendritic cells and innate lymphoid cells thus preventing the induction of type 2 cytokines IL-4, IL-5 and IL-13. Anti-TSLP treatment with tezepelumab decreased asthma exacerbations significantly [84] and phase 3 trials are ongoing.

The expression and production of Th2 cytokines IL-4, -5 and -13, have been shown in isolated cell systems and invertebrates to be controlled by the zinc finger transcription factor *GATA3*, which is essential for Th2-cell differentiation and activation and is considered to be the master transcription factor of the Th2 pathway of immune activation [85]. GATA3$^+$ Th2 cells have been observed in specimens from bronchoalveolar lavage and lung biopsies obtained from patients with severe asthma, even after continuous per oral corticosteroid [86]. CD2-Gata3 transgenic mice developed allergic airway inflammation and showed enhanced levels of IL-5 and IL-13 in bronchoalveolar lavage and lung tissue after allergen induction [87]. A novel therapy for the treatment of Th2-driven asthma targeted GATA3, a transcription factor that plays a key role in Th2 cell differentiation, through an inhaled DNA enzyme (DNAzyme) that specifically cleaves and inactivates *GATA3* mRNA. In a study of allergic asthmatic patients with sputum eosinophilia and biphasic early and late asthmatic responses after allergen provocation, inhalation of GATA3-specific DNAzyme once daily for 28 days attenuated both early and late asthmatic responses to allergen provocation when compared with placebo [88].

The protein encoded by *STAT6* gene is a member of the signal transducer and activator of transcription (STAT) family of transcription factors. In response to cytokines IL-4 and IL-13, STAT6 is phosphorylated by the receptor associated kinases, and then form homo- or heterodimers that translocate to the cell nucleus where they act as transcription activators for a large number of genes involved in macrophage polarization [89]. STAT6 has been demonstrated to regulate many characteristic features of lung inflammation common in asthma, including airway eosinophilia, epithelial mucus production, Th2 cell differentiation, and IgE production from B cells [90].

On chromosome 17q21, two intergenic variant SNPs between *CCR7* and *SMARCE1* associate with high p-value in GWAS reported by Ferreira et al. [40]. As mentioned above, the locus 17q21 is the most replicated in asthma GWASs, including many other important asthma genes such as *ORDLM3* and *GSDMB* [22]. The c–c-motif chemokine receptor CCR7 is a member of the G protein-coupled receptor family. It is responsible for the proper recruitment of lymphocytes and mature dendritic cells to lymphoid tissues. Dendritic cells, T-lymphocytes and B-lymphocytes express CCR7 on their surface, and it has been shown to promote the internalization of antigens by DCs, and to regulate cell survival, migration, and to induce dendritic cell maturation [91, 92]. Recent study investigated the effects of *CCR7* knockdown and overexpression on dendritic cell-mediated immune tolerance in the lungs of rats with allergic asthma and found that CCR7 expression levels affected the expression of various cytokines such as IL-12, IL-4, IFN-γ and IgE, as well as the amount of immune cells in the lungs [93].

FCER1A (Fc fragment of IgE receptor 1A), an initiator of the allergic response, is located on chromosome 1q23, next to *OR10J3* coding for an olfactory receptor, and showing more evidence on association. Variants in *FCER1A* has been reported to associate with total IgE levels, allergic sensitization [94] and atopy [95]. Association of *FCER1A* polymorphism with CRSwNP has been studied in North Indian population-based case–control study [96]. Although no significant association was found with CRSwNP alone, a significant association ($P < 0.05$) of rs2427827 SNP with high IgE level CRSwNP patients was revealed [96]. FCER1A has been shown to be expressed in mast cells and basophils as well as in monocytes and dendritic cells, and it has been suggested to have a dual role in IgE-signaling – studies conducted using transgenic mouse models have shown that on one hand, FCER1A expression induces type 2 inflammation in the lungs after viral infection, on the other hand it has been linked to regulatory role in asthma, promoting immune homeostasis (reviewed in [97]).

ADAD1—IL-2/IL-21: Hinds et al. report a SNP rs4145717-T in the 4q27 region that falls in the *ADAD1* gene, but the nearby *IL-2* and *IL-21* genes show more evidence on association [41]. In this region is another SNP associated with allergic rhinitis [98]. The IL-2 and IL-21 cytokines are involved in the regulation of multiple helper T cell types: IL-21 is needed for germinal center formation by generation of T follicular helper cells [99] and IL-2 is required for Th1, Th2 and Th17 cell differentiation [100].

Neuro-musculoskeletal function–related genes

C11orf30-LRRC32 region has been associated with asthma in previous studies [22]. *LRRC32* (also known as *GARP*, glycoprotein A repetitions predominant) (11q13) is expressed especially in lung and placenta and considered to be involved in several processes. It is a surface molecule of T regulatory cells [101] and earlier found in association to atopic dermatitis and induction of tolerance. C11orf30/EMSY is a transcriptional factor associating with tumor suppressor BRCA2, and it has been linked to above-mentioned TSLP activation in eosinophilic esophagitis [102]. In a multicenter population-based study, *C11orf30*-rs2155219 was reported to double the risk of polysensitisation [103]. Polysensitisation is associated to asthma [104]. *C11orf30/EMSY* has also been found a risk locus for both peanut and food allergy [105].

MYC encodes a transcription factor and located in the chromosome 8q24. MYC is a proto-oncogene and involved in Burkitt lymphoma and multiple myeloma and serves as a prognostic factor in acute myeloid leukemia [106]. A study showed that asthmatics have increased MYC expression in peripheral blood ILC [107]. They deleted *c-Myc* from murine lung ILC2 or an ILC2 cell line by CRISPR knockout, and showed reduced proliferation, decreased cytokine production, and reduced expression of many lymphocyte activation genes. In murine model of airway epithelial injury, *Myc* regulated proliferation and Fibroblast growth factor expression in airway smooth muscle [108].

Chromosomal area 6p21 (within the major histocompatibility complex gene) also includes Tenascin XB gene (*TNXB)* which is a member of tenascin family and extracellular matrix glycoproteins, and has musculoskeletal functions [55]. Tenascins are considered to be anti-adhesive and associated to wound healing, they have also been associated to Ehlers-Danlos syndrome and to malignant mesothelioma and are considered to be involved in airway remodeling in asthma [109]. Also the pre-B-cell leukemia homeobox 2 (*PBX2*) gene (rs204993), located in 6p21, is associated to both asthma and AR in Chinese population [110]. *PBX2* is expressed particularly in epithelium [110].

PSMD3 (chromosome 17q21) is a multicatalytic proteinase complex for proteasome and are distributed in many cells and have been reported to associate to atopic march and to atopic eczema and wheeze [111].

RAD50 (chromosome 5q31) is expressed in many tissues and needed for DNA double-strand break repair and other activities essential for cell growth. Further, it has been reported to associate with atopic dermatitis in Korean population [112]. *RAD50* has been shown to be expressed both in bronchial epithelial cells and bronchial alveolar lavage. However, *IL13*, locating in the same chromosomal region, showed more evidence on association with asthma [113].

RORA (chromosome 15q) is expressed especially in skin and adrenal gland and to less extent other tissues and is a member of NR1 subfamily of nuclear hormone receptors interacting in organogenesis and circadian rhythm [114]. Seven *RORA* SNPs were associated with childhood asthma in European populations, and *RORA* show epistasis with *NPSR1* [115]. The group showed in cell models that stimulation of NPSR1 activated RORA-relevant pathway [115], and that NPS induced *RORA* mRNA expression in neuroblast cell line [116].

The *RUNX* gene family encodes Runt-related transcription factors RUNX 1, 2 and 3. *RUNX3* (1p36) is expressed especially in bone marrow, lymph nodes and spleen and is involved in activating or suppressing transcription and is associated to tumor suppressor. *RUNX3* has been found to be hypomethylated and with increased association to inner city asthma in children [117]. RUNX1 is associated with aberrant B cell maturation and is related to acute myeloid or chronic leukemia [118]. Our study group showed that association between maternal smoking exposure and incident asthma in adult offspring was accentuated in offspring who had haplotype rs11702779-AA of *RUNX1* gene [119].

WDR36 (chromosome 5q22) encodes a member of the WD repeat protein family, involved in many cell functions e.g. signal transduction and apoptosis, and it has been associated with asthma and allergy [120–122]. In recent candidate gene analysis in Han Chinese population, it has been shown to associate with AR [123]. In vitro- studies show the involvement of WDR36 in G_q-coupled muscarine, bradykinin and histamine receptor signaling [124], all of which are important modulators of allergic reactions and asthmatic bronchoconstriction.

Other function–related genes

The Solute Carrier family members belong to the mitochondrial transporter family, which have an important role in metabolism [125]. The tissue distribution and cellular/subcellular expression of *SLC25A46* (Solute Carrier family 25 member 46) is ubiquitous [125]. A GWAS meta-analysis of 3933 European adults with allergic rhinitis and 8965 controls, and 2315 subjects with grass sensitization and 10 032 controls showed that a variant (rs2155219) located close to *SLC25A46* was associated with AR/grass sensitization [98]. The large GWAS of broad allergic disease phenotype (asthma and/or hay fever and/or eczema) by Ferreira et al. [40] identified also *SLC25A46* as one of the identified loci containing genetic risk variants independently associated with the risk of allergic diseas. A GWAS including Japanese and Korean pediatric asthma patients and controls, identified *SLC30A8* (Solute Carrier Family 30 member 8) SNP (rs3019885—> T/G) to associate strongly with pediatric asthma. *SLC30A8* is also known as Zinc Transporter 8, it is a zinc efflux transporter, highly expressed only in the pancreas, its variants are associated with diabetes mellitus type 2 [126]. It is not known how the Solute Carrier family members affect the risk of asthma.

LPP (Lipoma-preferred partner) is a member of a protein family regulating cytoskeletal organization, cell motility and mechanosensing and functions as a mediator of transforming growth factor β (TGFβ) induced cell migration and invasion in breast cancer cells [127]. A study group has found that the *LPP* gene (rs9860547, G->A) is a shared susceptibility locus of asthma and self-reported allergy, with the risk allele being protective against allergy in the meta-analysis of GWASs, in children and adults with self-reported allergy and controls [41]. The study group also performed eQTL analysis, the results of which suggested that the *LPP* gene association may be mediated by an effect on *BCL6* (B cell lymphoma 6) expression affecting STAT6-mediated responses on IL-4, IL-13, and IgE class switching [41].

Elevated sputum *PSORS1C1* (Psoriasis Susceptibility 1 Candidate 1) levels have been shown in chronic obstructive pulmonary disease (COPD) [128]. Pyrin and HIN domain family member 1 (*PYHIN1*) is related to initiation of innate immune response via detection of foreign DNA and, PYHIN1 was shown to positively regulate LPS-induced IFN-β and NO production through up-regulating the MyD88-independent signaling pathway in murine macrophage cell model [129]. Aquaporins (AQPs) mediate fast transmembrane transport of water thus regulating fluid balance in the organs [130]. *AQP2* gene encodes kidney´s water channel protein and it mediates urine water concentration and regulates water balance [130]. A mouse model showed that a Chinese herb, Platycodon root, by diffusing the lung can ameliorate the respiratory-function and pathologic changes in the lung tissues, but also regulate urinary output and renal expression of AQP1 and AQP2 [130].

PLCL1 (Phospholipase C-Like 1) is involved in an inositol phospholipid-based intracellular signaling cascade [41]. It has been reported to be related to Circadian entrainment [131] and Crohn's disease [41]. ABI3BP (ABI Family Member 3 Binding Protein) is a extracellular matrix protein and is expressed in multiple organs, including the heart, kidney, lung, pancreas, and placenta, with low-level or variable expression in the spleen, liver, brain, bone, and skeletal muscle [132]. *ABI3BP* gene has been shown to contribute emphysema phenotype in a mouse model that were exposed to cigarette smoke [133]. On the other hand a study showed that knockout of *Abi3bp* in mice does not affect their olfactory function, mental state and NNK-induced lung tumorigenesis [134]. *AP5B1* (Adaptor Related Protein Complex 5 Subunit Beta 1) is associated with Hereditary Spastic Paraplegia [135].

Conclusions

Development of post-GWAS methods are important for characterizing the function of trait-associated loci [136]. Strategies integrating various biological data sets with GWAS results will provide insights into the mechanistic role of associated loci. For example, an integrated GWAS and expression study on AR highlights mitochondrial pathways as a target for further investigation of AR mechanism and treatment [137].

We identified a total of 267 significantly asthma or AR –associating loci from 31 GWAS studies and 170 protein coding GWAS-level risk genes of asthma or AR. Of these about a third had airway epithelial functions in database and literature search. In addition, many genes have been related to immunity functions and in part to neuro-musculoskeletal and other functions in literature. These functions overlapped and also formed a strong network in pathway analyses. Still it is noteworthy that not all SNPs would be asthma markers themselves, or that each locus may lead to pathogenesis of AR or asthma. In addition, in about half of the protein coding genes the expression figures of databases was not yet available. Thus, further functional experiments would be needed to study their putative role in airways.

There is still scarce GWAS-level knowledge of CRS phenotype. After our GWAS catalogue search, a GWAS publication of Islandic and English CRS patients and controls showed that a missense variant in *ALOX15* causing p.Thr560Met alteration in arachidonate 15-lipoxygenase (*15-LO*) confers large genome-wide significant protection against CRSwNP and CRS. p.Thr560Met, carried by 1 in 20 Europeans, was previously shown to cause near total loss of 15-LO enzymatic activity [138]. The authors suggest that the protective effect of this variant is explained by inactivation of 15-LO´s catalytic activity, which leads to reduced production of pro-inflammatory mediators in eosinophils and nasal epithelium [138].

Since asthma and allergies are multifactorial disorders affected by both genetic and environmental factors and with multiple phenotypes, it seems likely that several genes are involved, each with a minor effect. It is expected that different genetic pathways are involved with varying proportions in different populations. Allergic diseases are also heterogeneous. Clinically, some patients have allergic rhinitis (AR) alone whereas others have AR and asthma (with or without other allergic manifestations). Few patients have asthma alone. Using transcriptomics analyses in European MeDALL birth cohorts and RNA sequencing in Puerto Rican children, AR as a single disease was found to be associated with Toll-like receptor gene expression (*TLR*), whereas rhinitis associated with asthma was linked with IL-5 and IL-33, confirming that the two diseases are different [139].

We show that many risk genes relate to leukocyte immunity or epithelial cell functions. Approximately half the patients with asthma, regardless of the severity of the disease, and majority of AR cases, exhibit Th2 endotype [67]. This endotype is characterized by a predominant activation of Th2 cells that produce cytokines such as IL-4, -5, and -13 [67]. There is increasing evidence of airway barrier´s role in airway diseases, such as AR [17]. Although expression profiles in upper and lower airways might differ [140], investigations on nasal epithelial interactions might provide additional knowledge for the lower airway inflammation [43, 141].

Therapeutic implications and future prospects

Since many of the identified risk genes for inflammatory airway diseases are airway epithelial or immunity function related, these functions should have an important role in the search for gene-environmental interactions, biomarkers and future therapeutics. Metabolism and neuro-musculoskeletal related functions also seem to have a central role in the development of asthma and AR.

With knowledge of important cascades in asthma and AR pathogenesis, as revealed also by these GWASs, it has been possible to develop medications that specifically target the key players of these cascades. In the 2010′s, biologics suppressing type 2 inflammation have become an important tool when tackling severe eosinophilic asthma, and recently also severe CRSwNP, and new substances are also under investigation [142].

Asthma endotypes can broadly be divided to type 2 high or type 2 low asthma [143]. Type 2 endotype is defined by the presence of Th2- and ILC2- inflammatory markers and eosinophilia. Type 2 low endotype is not as well defined; it is characterized by the absence of type 2 markers, and by activation of neutrophils, Th1 and/or Th17 cells [143]. Some patients, often with severe asthma, have a mixed population of airway granulocytes (eosinophils and neutrophils), and combined type 2 high and low cytokine signatures, such as IL-17 or IFN-γ [144]. This heterogeneity could explain why fewer genome-scale asthma loci have been identified in type 2 low asthma than in type 2 high asthma [143]. Lack of data also explains why molecules/pathways relevant to type 2 low asthma were discussed less in this review. Nevertheless, there are several mucosal molecules/pathways that are currently under investigation as potential therapeutic targets for type 2 low or mixed type of asthma, these include IL-6 [145] and TLR-3,4,7 [146].

After this study was performed, new GWASs and functional annotation analysis have been published with new interesting asthma loci such as TNF receptor superfamily member 8 (*TNFRSF8*) [143], and Collagen Type XVI Alpha 1 Chain (*COL16A1*) [147], and more studies are to come. This is indeed very important since further functional activity experiments of candidate genes are still needed to understand the dynamic molecular events behind the pathogenesis of airway diseases. In addition, there is a high need in the future to perform GWASs also on CRS, type 2 low asthma, chronic obstructive lung disease, and rare severe airway diseases, in order to broaden our understanding of all inflammatory airway disease subtypes and to discover new pathways/molecules. This knowledge would potentially improve future preventive and therapeutic strategies for inflammatory airway diseases.

Supplementary information

Supplementary information accompanies this paper at https://doi.org/10.1186/s13601-020-00347-6.

Additional file 1: Table S1. The full Excel file (as a supple file) of the results of ours including also the SNPs with no relevant signs of airway epithelial expression, and the PMIDs. There are several rows and they are based on 1) associated transcript for particular gene 2) allele changes 3) Multiple GWAS-studies that have shown the same loci. These explain the over 60 000 rows of the dataset. Abbreviations: N/A = not available, Protein_Atlas_Lung_Expression(TPM02) = 0 = TPM less than 1; 1 = 1 < TPM < 100; 2 = TPM 100 or over, Protein_Atlas_Lung_Expression(TPM) = total TPM value, HPA BrProt exp epi = Bronchial epithelial protein expression of immunohistochemical staining figures of The Human Protein Atlas, HPA Br Prot exp = Bronchial protein expression of immunohistochemical staining figures of The Human Protein Atlas, HPA Nasoph Prot exp epi = Nasopharyngeal epithelial protein expression of immunohistochemical staining figures of The Human Protein Atlas, HPA Nasoph Prot exp = Nasopharyngeal protein expression of immunohistochemical staining figures of The Human Protein Atlas, HPA Nasoph GTEx (RPKM) = The Genotype-Tissue Expression (GTEx) of Nasopharyngeal mucosa of The Human Protein Atlas, RPKM = Reads Per Kilobase of transcript, per Million mapped reads, HPA Bronch GTEx (RPKM) = The Genotype-Tissue Expression (GTEx) of Bronchial mucosa of The Human Protein Atlas, GXA = Gene Expression Database.

Additional file 2: Table S2. Integrated data from GWAS catalog on asthma, allergy/AR and CRS -associating SNPs, the corresponding proteins of which have evidence of human airway epithelial expression from manual literature search. The list of 170 asthma/AR –relevant coding gene names were identified based on GWAS search shown in Fig. 1. We detected that 145/170 genes have reported epithelial gene and/or protein expression based on systematic Human Protein Atlas (HPA) search. We detected that 86/170 genes have at least slight evidence of airway epithelial expression based on literature search, the citations are shown in the list. Abbreviations: Protein_Atlas_Lung_Expression(TPM02) = 0 = TPM less than 1; 1 = 1 < TPM < 100; 2 = TPM 100 or over, Protein_Atlas_Lung_Expression(TPM) = total TPM value, HPA BrProt exp epi = Bronchial epithelial protein expression of immunohistochemical staining figures of The Human Protein Atlas, HPA Br Prot exp = Bronchial protein expression of immunohistochemical staining figures of The Human Protein Atlas, HPA Nasoph Prot exp epi = Nasopharyngeal epithelial protein expression of immunohistochemical staining figures of The Human Protein Atlas, HPA Nasoph Prot exp = Nasopharyngeal protein expression of immunohistochemical staining figures of The Human Protein Atlas, HPA Nasoph GTEx (RPKM) = The Genotype-Tissue Expression (GTEx) of Nasopharyngeal mucosa of The Human Protein Atlas, RPKM = Reads Per Kilobase of transcript, per Million mapped reads, HPA Bronch GTEx (RPKM) = The Genotype-Tissue Expression (GTEx) of Bronchial mucosa of The Human Protein Atlas, GXA = Gene Expression Database, Literat_Resp_epith = Literature search result of Airway expression: 0 = no/not known; 1 = some evidence; 2 = evidence exists, Literat Ref (PMID) = PubMed ID for the Literature search result.

REVIEW

Deciphering the structure and function of FcεRI/mast cell axis in the regulation of allergy and anaphylaxis: a functional genomics paradigm

Abstract Allergy and anaphylaxis are inflammatory disorders caused by immune reactions mainly induced by immunoglobulin-E that signal through the high-affinity FcεRI receptor to release the inflammatory mediators from innate immune cells. The FcεRI/mast cell axis is potently involved in triggering various intracellular signaling molecules to induce calcium release from the internal stores, induction of transcription factors such as NF-kB, secretion of various cytokines as well as lipid mediators, and degranulation, resulting in the induction of allergy and anaphylaxis. In this review, we discuss various cellular and molecular mechanisms triggered through FcεRI/mast cell axis in allergy and anaphylaxis with a special emphasis on the functional genomics paradigm.

Keywords Allergy · Anaphylaxis · FcεRI · IgE · Cytokines · Transcription · Factors · Functional · Genomics

Introduction

The term *allergy* was first used in 1906 by Dr. Von Pirquet, an Austrian physician, to define an Immunoglobulin E (IgE)-mediated or type I hypersensitivity reaction triggered by allergens, which are antigens that bring out an allergic reaction [1]. In 1902, Richet and Portier [2] found that a dog tolerated the administration of sea anemone toxin initially; however, it died within few minutes of administering the second dose many weeks later. They coined the term *anaphylaxis*, which in Greek, *ana* means against; *phylax* means guard or protection. Richet was later awarded the Nobel Prize in Medicine and Physiology in 1913 for his work in anaphylaxis. At present, anaphylaxis refers to a life-threatening IgE-mediated allergic condition characterized by multiple organ involvement and quick onset. Drugs, insect stings, latex, and foods are the common allergens that trigger anaphylactic reactions. Very rarely, death due to anaphylaxis typically results from acute respiratory or heart failure.

Mast cells play a major effector role in the initiation as well as the propagation of various inflammatory disorders such as asthma, psoriasis, arthritis, etc. [3] and are the central effector cells in the mediation of allergy and anaphylaxis [4]. IgE-dependent or IgE-independent mast cell mediated response leads to the activation, synthesis and release of inflammatory mediators in allergy, and anaphylaxis [5–8]. In the past decade, scientists have been applying the microarray technology to explore the fundamental genetic causes of inflammatory conditions [9–13].

Such transcriptomic profiling immensely helps in our critical understanding of the global effects driven by the physiological “passive sensitization” or “active stimulation” of human mast cells to design novel therapeutic strategies to ameliorate and effectively manage both allergy and anaphylaxis.

Immunoglobulins and IgE

Defense against foreign bodies and microorganisms requires the interaction between innate immunity and acquired immunity. Generally, innate and acquired responses are regulated by humoral and cell-mediated responses. The humoral responses are mediated by immunoglobulins or antibodies, which are secreted by B lymphocytes. The immunoglobulins contain a variable Fab portion in the light chains and a constant Fc portion in the heavy chains. The Fab region interacts with a specific antigen and the Fc region binds to effector molecules such as Fc receptors and complement proteins. The ability of immunoglobulins to distinguish between a variety of antigens is due to the result of somatic recombination events, which result in the alteration of their variable regions. Based on the constant Fc region, immunoglobulins are subdivided into five major classes, which includes: IgG, IgM, IgA, IgE, and IgD. The effector molecules, which distinguish these immunoglobulins, are primarily Fc receptors, transport receptors and complement [14]. Every major immunoglobulin class has its own specific Fc receptor (FcR): FcαR binds IgA, FcεR binds IgE, FcγR binds IgG, FcδR binds IgD, and FcμR binds IgM [15–18].

IgE receptors and nomenclature

FcεRI-mediated reactions are the most prevalent form of immune-related diseases among humans. FcεRs play core function in the development of allergic inflammation. There are two types of IgE receptors: the high-affinity receptor (FcεRI) and the low-affinity IgE receptor (FcεRII; CD23) [19]. FcεRI is expressed on mast cells and basophils and on antigen-presenting cells whereas, FcεRII, a Ca-dependent lectin, is expressed on the surface of B cells, as well as other hematopoietic cells including Langerhans cells, macrophages, monocytes, eosinophils, and platelets. CD23, existing as CD23a and CD23b, has been associated with facilitating antigen presentation; it also negatively regulates IgE synthesis; and transports IgE-antigen complexes across epithelium [20]. Both IgE and IL-4 are shown to upregulate expression of CD23 [21].

Unbound FcεRI on the mast cell surface has a half-life of 24 h in vitro. On the other hand, FcεRI bound to IgE seem to be expressed throughout the life of the cell [22]. Aggregation of FcεRI by multivalent antigen results in several downstream intracellular signaling events linked with mast cell or basophil activation [23, 24]. When an allergen interacts with IgE that attached to mast cells or basophils by the α chain of the high-affinity IgE receptor, it will result in the activation of mast cells and release of both stored, as well as newly synthesized mediators (FcεRI*a*) [25]. Release of these mediators results in local vasodilatation, smooth muscle contraction, increased vascular permeability, and the initiation of inflammation. Such hypersensitivity reactions result in clinical manifestations including allergic rhinitis, atopic dermatitis, and anaphylaxis. In antigen-presenting cells (APCs), these receptors facilitate the IgE-mediated trapping and introduction of allergen to T cells [26, 27]. Eosinophils also have FcεRIa, but apart from activation and degranulation, it may aid in regulating local levels of IgE [28].

FcεRI: structure

FcεRI has a K_d of over 10^{-10} M binding affinity with monomeric IgE, which is the strongest when compared to the rest of the other Fc receptors for their ligands [29]. The classical form of FcεRI is tetrameric ($\alpha\beta\gamma_2$): constitutively expressed on mast cells and basophils in humans, while the trimeric form ($\alpha\gamma_2$) is present on the APCs such as monocytes, dendritic cells and Langerhans cells. The classical form consists of an IgE-binding α chain, a β chain, and a homodimeric γ chain. The β chain in FcεRI enhances receptor maturation [30] and the γ-homodimer enhances signal transduction [31]. Studies show that even in the absence of a β chain, the trimeric form of FcεRI possesses complete function [25, 32]. Both the β and γ chains are required for the efficient cellular expression of the FcεRI-α-chain [33]. In addition, studies have shown that $\alpha\gamma_2$ complexes were translocated to the periphery of the cell, meaning that the human γ chain by itself is sufficient to fight against endoplasmic reticulum retention signals in the α chain [33].

FcεRI effector cells: mast cells and basophils

Mast cells have been considered as the most vital effector cell type for allergic conditions including, to a lesser extent, basophils and neutrophils [34, 35]. The progenitors for mast cells migrate into the peripheral tissue and undergo differentiation to become mature mast cells in situ. They are mainly located within blood vessels and the epithelial lining. Mast cells of hematopoietic origin respond to signals of both innate and acquired immune response with immediate and delayed release of inflammatory mediators. Based on their site of location and granule contents, mast cells are divided into connective tissue mast cells and mucosal mast cells. Human connective tissue mast cells are observed in the skin and intestinal sub-mucosa, and their granules comprises tryptase and chymase. Studies have also shown that the granules of tryptase were found in the mast cells located in intestinal mucosa and alveoli [36]. Mast cells are central to the pathogenesis of type I hypersensitivity and mastocytosis. Mast cells are also entailed with self-responses to pathogens, autoimmune diseases, and fibrosis. Eicosanoids and cytokines are synthesized by mast cells and contribute to inflammation. Mast cells can be specifically stained with basic dyes such as toluidine blue [37].

Basophils also express high levels of FcεRI. They are derived from CD34$^+$ hematopoietic progenitor cells and play a vital role in the host defense against parasitic infections, as well as mediating type I hypersensitivity reactions. Basophils are present in blood as mature forms. However, they can be recruited to the site of inflammation where antigens are located. Cytoplasmic granules in the basophils comprise pro-inflammatory mediators. Because basophils share structural and functional similarities with mast cells, they trigger comparable effector responses as observed in mast cells upon aggregation of FcεRI. Apart from basophils and mast cells, FcεRI is also found to be expressed in low levels on eosinophils, monocytes, platelets, dendritic cells, and Langerhans cells [25].

Mast cells: morphology

Mast cells are up to 20 μm in diameter, are ovoid or irregularly elongated in shape [38]. Mast cells contain ample metachromatic cytoplasmic granules and they can be stained because of large sulfated proteoglycans in the granules. Tryptase staining detects all mast cell types and is the principal method for detecting tissue mast cells. The granule contents are crystalline under the electron microscope, but turn formless upon activation and before degranulation. Mast cells express several receptors including IL-3R, IL-4R, IL-5R, IL-9R, IL-10R, GM-CSFR, IFN-γR, C3a and C5a receptors, CCR3, CCR5, CXCR2, CXCR4, nerve growth factor receptor, Toll-like receptors (TLRs), and ST2 [39, 40].

FcεRI-mediated signal transduction

Interpreting the intracellular signaling cascade mediated by mast cell activation has major therapeutic implications for inflammatory conditions. FcεRI aggregation and mast cell activation has long been known to be an important incident in allergic conditions [41–43]. Numerous studies have focused on the intracellular signaling cascade mediated by mast cell activation and release of pro-inflammatory mediators [25, 44, 45]. Figure 1 shows the schematic representation of FcεRI-mediated intracellular signaling events. Following cross-linking of FcεRI, intracellular signal transduction is initiated by a tyrosine kinase, named Lyn, which is constitutively linked with the FcεRI receptor [46, 47]. Subsequently, Lyn phosphorylates the immunoreceptor tyrosine-based activation motif (ITAM) of the subunits of the FcεRI, leading to the activation and binding of protein tyrosine kinases (PTK) with Src homology domain 2 (SH2). One such PTK is spleen tyrosine kinase (Syk) [48]. An activated Syk subsequently leads to further tyrosine phosphorylations of several "adapter" proteins including that of linker for activation of T cells (LAT) as well as phosphorylation of phospholipase C γ (PLC-γ).

LAT phosphorylation leads to the activation of JNK and ERK; and the synthesis and release of cytokines and arachidonic acid (AA) metabolism result in target organs to cause the clinical syndrome of anaphylaxis [49]. On the other hand, phosphorylated PLC-γ yields diacylglycerol (DAG) and inositol-1,4,5-triphosphate (IP$_3$) from membrane phospholipids. DAG successively activates protein kinase C (PKC), which results in the exocytosis of stored granules and cytokine release.

Furthermore, Bruton's tyrosine kinase (Btk) is membrane targeted and activated by the binding of phosphatidylInositol-3, 4, 5-trisphosphate (PIP3) moiety to its Pleckstrin-Homology (PH) domain. Btk then phosphorylates and activates PLC-γ [50]. On the other hand, the induction of PI3 K by Syk results in the production of micromolar levels of PIP2 and PIP3. Besides, PI3 K is essential for the induction of intracellular Ca^{2+} release as well as mobilization across plasma membranes. Both PI3 K and PLCγ act synergistically on the common substrate PIP2 to produce PIP3 and IP$_3$, respectively. The IP$_3$ activates Ca^{2+} channels at different cellular compartments, primarily in the endoplasmic reticulum [ER], to release Ca^{2+} required for optimal physiological responses. As a result, the depletion of Ca^{2+} in the internal stores causes the influx of Ca^{2+} from the extracellular space through the activation of a type of store operated Ca^{2+} channel (SOCC) termed as Ca^{2+} release activated Ca^{2+} channel (I_{CRAC}) [50, 51, 52].

Studies have shown that cross-linking of FcεRI in rat basophilic leukemia cells activates sphingosine kinase, which produces sphingosine-1-phosphate (S1P). S1P is a potent sphingolipid mediator, and acts as a second messenger in releasing intracellular calcium from internal stores. This process is carried through the inositol 1,4,5-triphosphate (IP$_3$)-independent pathway [53]. Studies report that aggregation of FcεRI in human bone marrow-derived mast cells resulted in the activation of PLD1, leading to downstream activation of SPHK1 [54]. This process results in the initial release of intracellular calcium as well as degranulation of mast cell(s). Another interesting

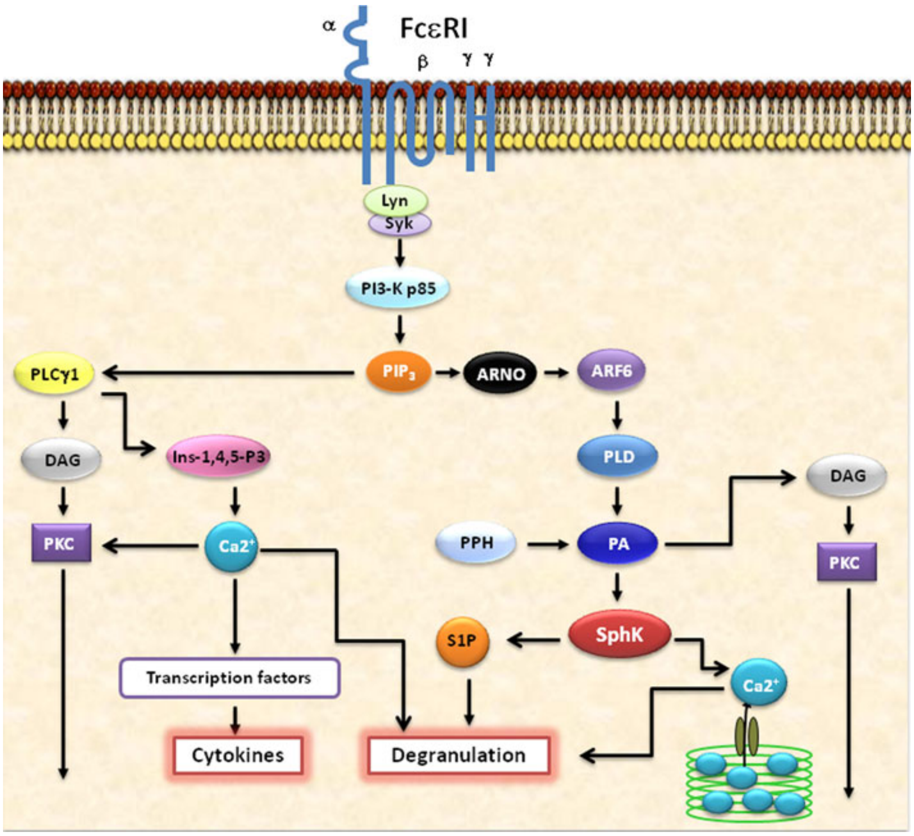

Fig. 1 Schematic representation of FcεRI-mediated intracellular signaling events in mast cells and basophils. The allergen cross linking of FcεRI receptors initiate key cellular signaling events such as the activation of PLCγ, PKCs, SPHKs, PI3Ks, etc. An important role for these major pathways in immune cell function is predicted based on their ability to regulate the transcriptional activity of cytokine genes, calcium release from the internal stores which is essential for the degranulation and further intracellular mediation of signaling processes, and the production of lipid mediators such as prostaglandins and leukotrienes. The specific blocking of these key intracellular signaling molecules such as PLCγ, PKCs, SPHKs, S1P, PI3Ks, etc., by specific chemical inhibitors or siRNAs, or therapeutic Intrabodies would certainly be of immense use in the effective management of allergy and anaphylaxis in the near future

study reports that blocking SPHK activity forbids FcεRI-mediated internalization of S1P receptors and significantly reduces degranulation [55]. Also, tyrosine kinase Lyn has been shown to be associated with recruitment and activation of SPHK to FcεRI [56].

FcεRI: regulation

In 1978, Malveaux et al. [57] reported for the first time that the presence of circulating monomeric IgE could raise FcεRI cell surface expression. Many studies have been published in the 1990s showing IgE drives FcεRI expression in both human and murine mast cells, as well as basophils [58–60]. These reports have helped in understanding the mechanisms of IgE sensitization, during which FcεRI is over-expressed at cell surface, and FcεRIs bound to IgE are activated when re-exposed to allergens. FcεRI expression as well as mast cell activation upon cross-linking IgE-bound FcεRI with polyvalent antigen lead to degranulation [34, 61]. Such IgE-mediated mast cell recognition of multivalent antigen and the subsequent intracellular signaling events are well studied in various inflammatory models [62–65].

IgE-mediated FcεRI expression was also observed in monocytes [66, 67]. However, monocytes do not express FcεRIβ and are shown to express low levels of FcεRI. FcεRIβ appears to be playing a key role in the receptor expression and has also been shown to be associated with atopic diseases [68]. A single-nucleotide polymorphism (SNP) in the FcεRIβ gene has been connected to higher IgE serum levels and result in the increased FcεRI surface expression [69]. In IgE-mediated FcεRI regulation, over-expression of receptor is caused by the interaction of IgE with the receptor [70]. The total FcεRIα content increases with surface receptor up-regulation. On the other hand, the removal of IgE results in the reduction in the receptor expression, as well as FcεRIα content [71]. Though the actual mechanism still remains unclear, IgE-FcεRI binding enhances the surface expression of FcεRI [72]. Reports show that FcεRI receptor expression in mast cells are mediated by IL-4 [60, 73]. On the whole, the factors that mainly affect the expression of FcεRI are the expression of FcεRIβ and the serum levels of IgE [60, 73].

FcεRI: biological functions

FcεRI triggers IgE-mediated activation and degranulation of mast cells and basophils. Apart from mediating type I hypersensitivity reactions, FcεRI plays other biological roles, too. First of all, FcεRI and IgE are vital for the self-defense against parasitic infections [74]. In vivo studies showed that mice lacking α chain of FcεRI were also protected against parasitic infections like the normal mice. However, it is not very clear why and how the absence of functional FcεRI/mast cell axis protects these mice against parasitic infections [74]. Interestingly, very recent study has partially answered the above statement by showing that the IgG/neutrophil axis is also key for the triggering of passive and active systemic anaphylactic shock in mice [35].

The other biological role of FcεRI is their expression on APCs such as dendritic cells and monocytes [75]. FcεRI is expressed as $\alpha\gamma_2$ form on the APCs. It is known that the $\alpha\gamma_2$ structure may assist in targeting antigen-IgE-FcεRI complexes to the intracellular antigen-presenting compartment. The IgE-dependent type of antigen presentation will make sure that it will only amplify the immune responses, which were already mediated by IgE. This type of antigen presentation can mediate cytokine production from APCs and thus, helps to modulate allergic inflammation [20, 25].

Activation of mast cells and release of mediators

The mediators released by the mast cells can be categorized into three main groups: preformed granule content, membrane derived lipid mediators, and cytokines [76–78]. Figure 2 shows the schematic representation of major types of mediators released by the mast cells. Histamine is the most clinically evident preformed granule mediators responsible for the acute symptoms. Histamine is shown to be associated with immediate type I hypersensitivity reactions [79]. The level of histamine that is produced and stored in mast cells is roughly 1 or 2 pg/cell. Histamine receptors are further classified into H_1, H_2, and H_3. H_1 receptor stimulation results in bronchial smooth muscle contraction, increased vascular permeability, nasal mucus secretion, and increased neutrophil and eosinophil chemokinesis and chemotaxis. On the other hand, H_2 receptor stimulation results in ventricular and atrial contraction, gastric acid production, airway mucus secretion, and vascular permeability as well as inhibition of basophil histamine release. Finally, H_3 receptors, which are found to be in neurons and peripheral tissues, regulate the secretion and synthesis of histamine.

Membrane-derived lipid mediators and cytokines are synthesized upon activation of mast cells. Prostaglandin D_2 (PGD_2) is the key arachidonic acid (AA) lipid metabolite released upon mast cell activation. PGD_2 is synthesized from AA by the cyclooxygenase pathway and is responsible for causing bronchospasm, hypotension, and inhibition of platelet aggregation. PGD_2 is roughly over 30 times more potent than histamine, especially in causing bronchoconstriction. Leukotrienes are slow-responding substances of anaphylaxis. Leukotrienes—LTB_4, LTC_4, LTD_4, and LTE_4 are synthesized from AA through the lipoxygenase pathway. Leukotrienes have been shown to be linked in increased vascular permeability, increased mucous gland production and cholinergic-independent bronchospasm. Leukotrienes have a slow onset but are 10–1,000 times added potent, compared to histamine in developing bronchoconstriction when dispensed by aerosol [80]. The other most potent compound and unstored phospholipid is platelet-activating factor (PAF). PAFs are known to cause aggregation of human platelets and release of platelet-derived vasoactive mediators. PAF has been implicated with anaphylaxis, including pulmonary edema and coronary vasoconstriction [81, 82]. Studies show that the blockade of PAF with inhibitors result in improved cardiac function, suggesting a key role for PAF in cardiac dysfunction [83]. Furthermore, TNF-α is a major cytokine that is in both stored as well as synthesized forms [84]. It over-expresses cell adhesion molecules, increases bronchial responsiveness, and also possesses antitumor effects. Other cytokines produced by mast cells include IL-1, IL-3, IL-4, IL-5, IL-6, and IL-8 [39].

Mast cells in acute and chronic allergic reactions

Mast cells play a central role in the initiation and development of atopic allergic reactions. The intracellular signaling events have been broadly studied on mast cells not only to know their physiological roles but also to find potential therapeutic targets. Type I hypersensitivity is the fundamental of acute allergic conditions [85]. It is stimulated by molecules released by mast cells when an allergen or antigen cross-react with membrane-bound IgE.

Allergic conditions broadly consist of two phases: sensitization and elicitation phase [86]. In the self, sensitization occurs upon the initial exposure to an allergen or antigen. Dendritic cells and macrophages are the first line of defense against antigens through phagocytosis and cell-mediated uptake of antigens. The antigen is degraded by the antigen-processing pathway and subsequently

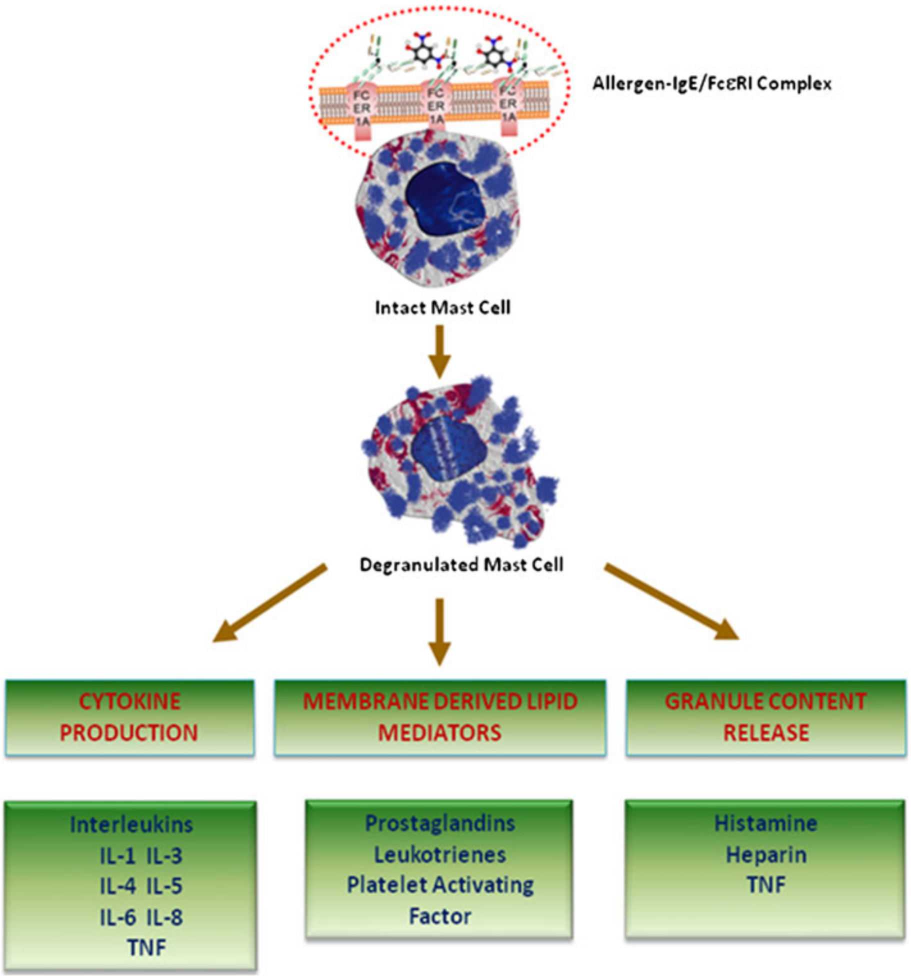

Fig. 2 The key mediators of FcεRI/Mast cell axis in allergy and anaphylaxis. The schematic representation illustrates some of the key mediators released by the mast cells upon stimulation during allergy and anaphylaxis. The mediators released by the mast cells can be categorized into three main groups: preformed granule content, membrane-derived lipid mediators, and cytokines

presented as a component of the MHC class II complexes [87]. Then the mature dendritic cells stimulate naive T cells to differentiate into either T_H1- or T_H2-type $CD4^+$ T cells [88], which aids in the maturation of B-cells to IgE secreting plasma cells. FcεRI aggregation triggers the release of pre-formed mediators, production of lipid mediators and cytokines. In an atopic condition, exposure of the nose, skin, or airway to an initial dose of allergen triggers a cutaneous reaction, results runny nose, sneezing, and wheezing in minutes. In case of asthma, these mediators develop acute reactions, including mucus production and smooth muscle contraction. This depends upon the type I immediate allergic reactions and subsequently followed by a chronic allergic reaction, which peaks 6 to 9 h post-initial exposure [89]. The cellular pathways leading to acute and chronic allergic reactions are shown in Fig. 3.

A T_H2 response has been observed in an atopic condition and IgE production will result in binding with FcεRI on the effector cell. This will in turn increase the efficacy during re-exposure to the same allergen [90–92]. During the late-phase reaction of the skin, neutrophils and eosinophils accumulate, followed by $CD4^+$ T cells and basophils that infiltrate to the site of inflammation [93]. The late-phase asthmatic condition also shares a similar pattern of cellular infiltration [94–96]. However, basophils are not mainly infiltrated into the lower airways [97, 98]. Studies also show that further amplifications of chronic allergic reactions may be mediated by histamine-releasing factors [99, 100]. Cross-linking of mast-cell-bound IgE with an antibody against IgE elicits both type I and late-phase reactions [101–104]. The immediate and delayed phases of bronchial hypersensitivity are initiated by mast cells are shown in both humans, as well as in mouse models of asthma [105, 106]. It has been reported that mast cells may also be associated with regulating the early stages of autoimmunity, especially in [107–109] diseases where auto-antibodies play a vital role [110].

High-throughput functional genomics paradigm

The latest developments of functional genomics tools, such as genome-wide transcriptomic analysis have revolutionized the approaches to answer complex scientific problems.

T-Cell Receptor (TCR)

Fig. 3 The cellular pathways leading to acute and chronic allergic reactions. The binding of allergen with IgE/FcεRI complex on mast cells triggers the release of pre-formed mediators, production of lipid mediators, and cytokines leading to acute allergic conditions. Allergic conditions broadly consist of two phases: sensitization and elicitation phase. In the self, sensitization occurs upon the initial exposure to an allergen or antigen. Dendritic cells and macrophages are the first line of defense against antigens through phagocytosis and cell-mediated uptake of antigens. The antigen is subsequently degraded as a component of the MHC class II complexes. Then the mature dendritic cells stimulate naive T cells to differentiate into either T_H1- or T_H2-type $CD4^+$ T cells, which aids in the maturation of B-cells to IgE-secreting plasma cells. Chronic allergic reactions, including the late-phase reaction, may rely on a combination of events and the release of mast-cell products by histamine-releasing factors from T-helper cells

Table 1 Overview of gene expression studies performed using mast cell lines and primary mast cells

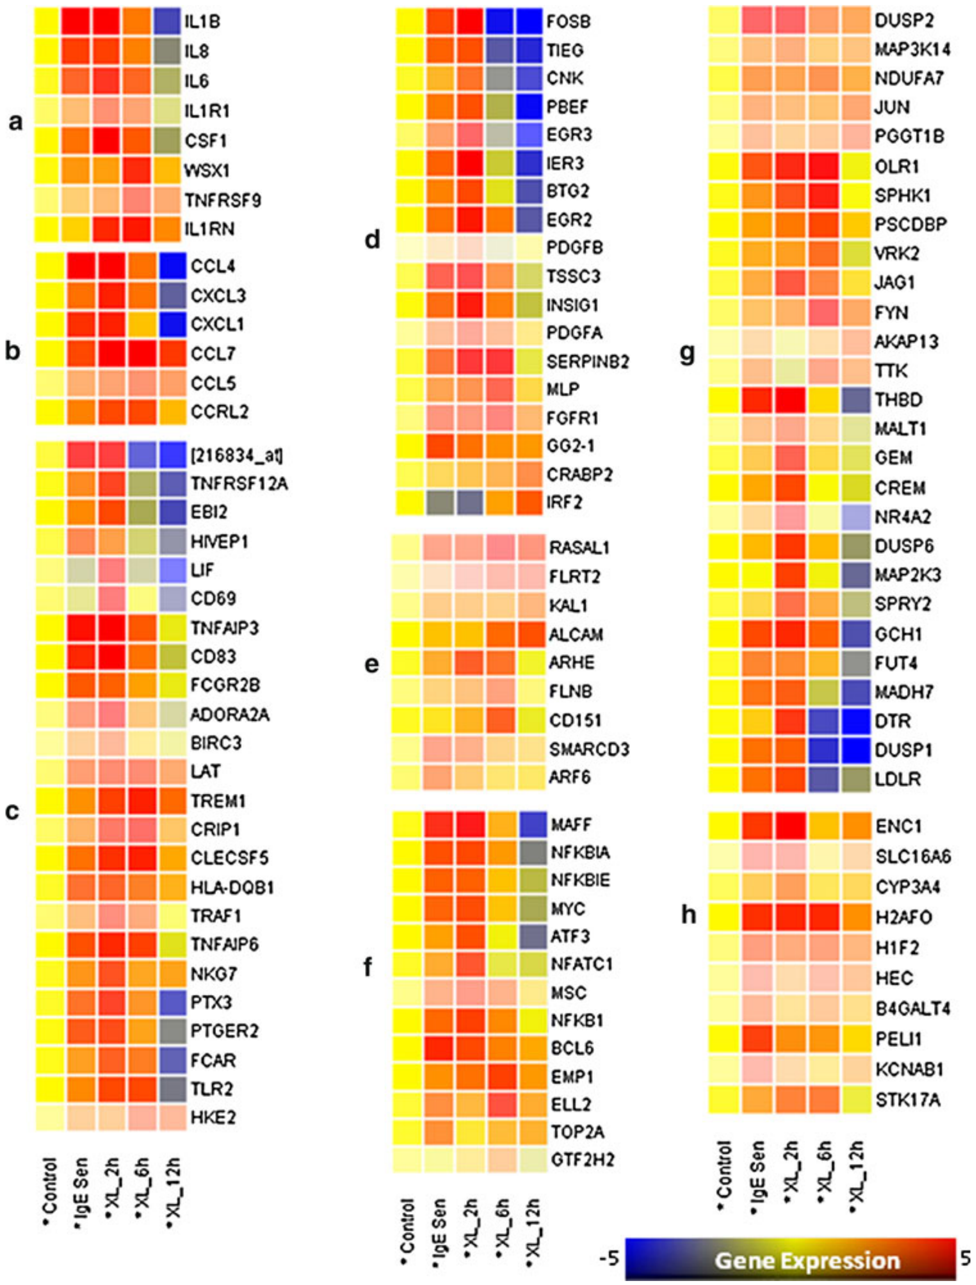
Study	Source	Stimulation	Platform	No. of genes
[116]	HUCBMCs	No stimuli	RT-PCR	32 genes
[117]	HUCBMCs	No stimuli	SAGE, RT-PCR	9,000 tags- SAGE
[118]	Human PBMNC-MCs	IgE + Anti IgE	ELISA, RT-PCR	Cytokines and chemokines
[119]	HUCBMCs, eosinophils, neutrophils and PBMNC	No stimuli	ONT array	6,000 probes
[120]	RBL-2H3	IgE + DNP	ONT array	8,799 probes
[121]	BM-mouse MCs	IgE + DNP	ELISA	Cytokines
[122]	Human lung MCs	TLR4	QPCR, ELSIA	Cytokines
[123]	Human Skin MCs	IgE or PMA	ELISA, RT-PCR	Cytokines
[124]	HUCBMCs	IgE	ELISA	IL-8 & MCP-1
[115]	HUCBMCs	IgE	ONT array	8,763 probes

The above evidence table depicts the authors of the study, source of mast cells used, stimulation method for activation of mast cells, platforms used for gene expression profiling, and number of genes screened.

MC mast cell, *HUCBMCs* human umbilical cord blood-derived mast cells, *PBMNC* peripheral blood mononuclear cell culture, *RBL-2H3* rat basophilic leukemia cells

Several groups have carried out low, medium, and high-throughput transcriptomic analysis of mast cell-mediated expression profiling, furnishing some novel pathogenic mechanisms of mast cell-mediated allergic responses. Table 1 shows various gene expression studies carried out on mast cells. The impact of these studies confirms that the mast cell stimulation and activation seem to be associated with number of pathologies including allergy and other

Fig. 4 Gene expression pattern in human mast cells following IgE sensitization and FcεRI aggregation. The raw Affymetrix GeneChip data was downloaded from gene expression omnibus (GSE1933) and normalized with parametric test based on cross gene error model (PCGEM) and subjected to one-way ANOVA and Bonferroni-Hochberg FDR ($p < 0.05$) using Genespring 7.3 The differentially expressed genes by the IgE sensitization and FcεRI cross-linking for different time points (2, 6, and 12 h) were then classified and clustered based on gene ontology (GO). Analysis to decode the differentially expressed genes implicated in biological processes such as **a** cytokines and cytokine receptors, **b** chemokines and chemokine receptors, **c** other immunoregulatory genes, **d** cell proliferation and apoptosis, **e** adhesion and cytoskeleton remodeling, **f** transcription factors and regulators, **g** signal transduction, and **h** other genes [115]



immune/inflammatory conditions. A number of studies on immune/inflammatory response show the usefulness of transcriptomic analysis to understand the underlying molecular mechanisms [11, 111–114]. With transcriptomic analysis coupled with stringent statistical measures, we show the genome-wide expression patterns of differentiated human mast cells stimulated by IgE sensitization, and FcεRI aggregation at different time points. In our earlier study, we have elucidated the molecular events which the differentiated human mast cells go through upon IgE sensitization and after complete activation in a genome-wide manner [115]. Generation of a wide-variety of cytokines and chemokines upon IgE-sensitization and FcεRI aggregation on mast cells suggests that they could be the key regulators of the immune response (Fig. 4). It may also lead to the recruitment and activation of other effector cells to the site of inflammation, which may further enhance the progression of immune response [115].

FcεRI/mast cell axis: pathway analysis of differentially expressed genes

Representation of specific inflammatory and immunoregulatory pathways among the differentially expressed genes [115] was analyzed using Pathway Studio® software

Fig. 5 Molecular pathways triggered through FcεRI/mast cell axis. Representation of specific inflammatory and immunoregulatory pathways among the differentially expressed genes triggered through FcεRI/mast cell axis was analyzed using Pathway Studio® software (Ariadne Genomics, Rockville, MD) version 6.0. The software uses information available in the current literature to identify common pathways, targets, or regulators that are associated with the altered genes to generate biological interaction networks. Genes were linked to each other based on the published literature

(Ariadne Genomics, Rockville, MD) version 6.0. The software uses information available in the current literature to identify common pathways, targets, or regulators that are associated with the altered genes to generate biological interaction networks. Microarray expression data was imported into Pathway Studio® to graphically represent all known relationships and potential interactions between the differentially expressed genes. Pathway Studio software was used to identify a possible gene network that is differentially regulated in the mast cell-mediated classical pathway. Genes were linked to each other based on the published literature (Fig. 5).

Concluding remarks

Allergy and anaphylaxis comprise a wide spectrum of pathologies associated with the inappropriate activation of the immune system by environmental antigens [125]. Allergic responses to foods, insect bites, oral and injected medications, and other agents, remain huge problems, and are constantly increasing in society [125, 126]. Importantly, the FcεRI/mast cell axis is central to these immune reactions, and provides an attractive target for the inhibition of all IgE-mediated allergic diseases. Moreover, the modulation of this central axis has long been considered as a therapeutic strategy for various allergic disorders [50, 127]. Interestingly, clinical studies of allergic individuals using anti-IgE monoclonal antibody therapy have shown that the exploitation of this key axis is an effective approach to disease treatment [128, 129].

In addition, mast cells play a major role in the pathogenesis of inflammatory diseases such as asthma, atopic dermatitis, psoriasis, and interstitial cystitis, as well as a minor role in irritable bowel syndrome (IBS), inflammatory bowel disease (IBD), rheumatoid arthritis (RA), coronary artery disease (CAD), obesity, multiple sclerosis, and cancer [3, 4, 130]. As a result, the critical dissection of differentially expressed genes triggered through the FcεRI/mast cell axis and extensive exploration of their regulatory pathways through advancing high-throughput technologies, may allow us to selectively regulate these processes and help in the development of therapeutic modalities to potentially control and manage the exaggerated immune/inflammatory responses in allergy and anaphylaxis in the near future.

Acknowledgments The authors would like to thank the various research groups around the globe for their exceptional contributions in the basic, translational, and clinical aspects of allergy and anaphylaxis. We really regret the omission of any of these findings or contributions on the FcεRI/Mast cell axis in this review, which is mainly due to space limitations. We extend our immense appreciation to the graphics team of Beacon Biosoft (www.beaconbiosoft.com) for the fantastic figures in our review.

Abstract

Asthma is a common, clinically heterogeneous disease with strong evidence of heritability. Progress in defining the genetic underpinnings of asthma, however, has been slow and hampered by issues of inconsistency. Recent advances in the tools available for analysis—assaying transcription, sequence variation, and epigenetic marks on a genome-wide scale—have substantially altered this landscape. Applications of such approaches are consistent with heterogeneity at the level of causation and specify patterns of commonality with a wide range of alternative disease traits. Looking beyond the individual as the unit of study, advances in technology have also fostered comprehensive analysis of the human microbiome and its varied roles in health and disease. In this article, we consider the implications of these technological advances for our current understanding of the genetics and genomics of asthma.

INTRODUCTION

Asthma is a chronic disease of the airways defined by its symptoms, which include reversible airflow obstruction, inflammation, and bronchial hyperresponsiveness. The ancient Egyptians, Greeks, and Romans made reference to the symptoms of asthma, and today the disease is estimated to affect 235–334 million people worldwide (44, 53).

Asthma is heterogeneous in both its clinical presentation and its prognosis. The International Classification of Diseases diagnostic system primarily groups asthma patients according to the severity and persistence of symptoms and the presence of complications (152). Statistical approaches to subtype asthma likewise observe substructure among symptoms (such as atopic status, wheeze, and cough) (67), but the nature of this structure may depend on choices relating to variable inclusion and methodology (34), limiting the overall clinical application of such phenotype-driven techniques.

Asthma has a substantial genetic component, with estimates of heritability ranging from 35% to 95% (116). As such, the genomic era brought with it hopes of molecular subtyping and associated personalization of treatment plans for the disease, as has been seen in the case of breast cancer (20, 28). However, given that the heritability of asthma is incomplete (<1), environmental factors must also account for a fraction of the phenotypic variance. Consistent with this, epidemiological studies have identified a range of pre-, peri-, and postnatal environmental factors, including mode of delivery, diet, and early lower respiratory tract infection, that confer relative risk or protection. Attempts to map the genetic architecture of asthma have identified a broad spectrum of potential contributory genes. Many of these genes demonstrate inconsistent patterns of replication between cohorts, most likely reflecting a combination of true positive and true negative results and the unseen hand of gene × environment and gene × gene interaction. Nevertheless, a handful of genes have shown robust association with asthma. While these effects individually account for only a minority of phenotypic variance, they provide novel insights into the underlying pathogenic processes as well as potential sources of interaction with the environment. Here, we review the genetic and genomic factors that are currently implicated in the pathobiology of asthma and consider the ability of these factors to differentiate between patient groups.

GENETIC LINKAGE AND POSITIONAL CLONING

Prior to the advent of high-throughput technologies, the cost of genotyping was substantial. As such, genome-wide, hypothesis-free approaches were limited to relatively small panels of informative (multiallelic) markers distributed approximately evenly across the genome. Genotype at these sites was determined in families with multiple affected individuals, allowing identification of contiguous regions that showed co-transmission with the trait of interest. Broad loci specified as harboring susceptibility variants could then be explored at a higher resolution through positional cloning or positional candidate gene studies, ideally identifying genes or the individual sequence variants responsible. This technique, highly successful in the arena of Mendelian traits, was the mainstay of early genetic studies of asthma, with more than 25 such studies reported between 1996 and 2006 (reviewed in 18, 35). While these studies led to the identification of only eight genes, *ADAM33*, *DPP10*, *PHF11*, *NPSR1*, *HLA-G*, *CYFIP2*, *IRAK3*, and *OPN3* (3, 11, 78, 112, 114, 142, 151, 162), that putatively contribute to the genetic etiology of the disease, each of small effect, all but one were novel, with no previously suspected role in asthma.

The eight positionally cloned putative susceptibility genes (listed in **Table 1**) are diverse in their described functions, ranging from cytokine and chemokine processing (*DPP10*) (3) to class-switch recombination (*PHF11*) and airway remodeling (*ADAM33*). *ADAM33* was the first gene

Downloaded from www.annualreviews.org. Guest (guest) IP: 24.117.150.43 On: Tue, 14 Oct 2025 03:05:08

Table 1 Positionally cloned putative asthma genes and their signals in genome-wide association studies

Positionally cloned gene	Region	Description	Mapped traits accompanied by low *p* values
ADAM33 (ADAM metallopeptidase domain 33) (142)	20p13	Metalloprotease	None
DPP10 (dipeptidyl peptidase–like 10) (3)	2q14	Serine protease	Severe influenza A (H1N1) infection (51), response to antidepressants in depression (83), survival in microsatellite instability low/stable colorectal cancer (154), gut microbiome composition (winter) (30), subjective well-being (117), systolic blood pressure in sickle cell anemia (15), bipolar disorder (71), obesity-related traits (25), response to paliperidone in schizophrenia (negative Marder score) (82), and suicide attempts in major depressive disorder (50)
PHF11 (PHD finger protein 11) (162)	13q14	Double-stranded DNA–binding protein	Breastfeeding duration (24) and cardiac hypertrophy (119)
NPSR1 (neuropeptide S receptor 1) (78)	7p14	G-protein-coupled receptor	IgG glycosylation (81), postbronchodilator FEV1 (94), and postbronchodilator FEV1/FVC ratio (94)
HLA-G (major histocompatibility complex, class I, G) (112)	6p21	Major histocompatibility complex antigen	Autism spectrum disorder or schizophrenia (10), eosinophil percentage of granulocytes (9), eosinophil percentage of white cells (9), neutrophil percentage of granulocytes (9), Crohn's disease (75), lung adenocarcinoma (103), IgE levels (57), and childhood ear infection (123)
CYFIP2 (cytoplasmic FMR1-interacting protein 2) (114)	5q33	G-protein modulator	Lung function (FEV1/FVC) (144) and IgG glycosylation (81)
IRAK3 (interleukin 1 receptor–associated kinase 3) (11)	12q14	Kinase	Smooth-surface caries (160)
OPN3 (opsin 3) (151)	1qter	G-protein-coupled receptor	Daytime sleep phenotypes (134)

This table summarizes the genes positionally cloned for asthma per se and includes their genomic location. The publicly available GWAS Catalog (19) was systematically queried for these genes, and traits accompanied by a p value $\leq 5 \times 10^{-6}$ at the time of writing are listed. Abbreviations: FEV1, forced expiratory volume measured during the first second of forced breath; FVC, forced vital capacity.

to be positionally cloned for asthma. Its transcripts show a preferential distribution in cells of mesenchymal origin (139, 142), and its sequence variants associate not only with asthma per se but also with bronchial hyperresponsiveness, early-life lung function, lung function decline across the life course, and chronic obstructive pulmonary disease (31), consistent with the gene's proposed role in airway remodeling.

Unfortunately, as with many other so-called complex (or multifactorial) traits, positionally cloned putative asthma susceptibility genes have been hampered by issues of inconsistent replication. While there are a host of competing explanations for this phenomenon, contributory factors may include false positives, allelic heterogeneity, natural variation in linkage disequilibrium between causative and genotyped sequence variants among assayed populations, the effects of other genetic variants and environments, and/or gene × gene or gene × environment interactions. By way of example, in 2003 *PHF11* was posited to be responsible for the chromosome 13q14 linkage peak that influences asthma and total serum immunoglobulin E (IgE) levels, as variants within this gene demonstrated the strongest evidence of association with the tested traits (162). Consistent with this hypothesis, *PHF11* was also shown to accelerate class-switch recombination to IgE in murine activated B cells (68). Although the chromosomal interval that contains *PHF11* has been implicated in asthma, atopy, and IgE traits in several linkage studies and the association between *PHF11* and asthma has been independently replicated, replication has not been successful across the full range of populations tested (101). Within the genome, *PHF11* is positioned in a linkage disequilibrium block that includes both *PHF11* and its immediate physical neighbor, *SETDB2* (SET domain bifurcated 2). These two genes, separated by an interval of just 4 kb, are transcribed in the same direction and form fusion transcripts in some tissues (162). A recent analysis of this region identified a functional variant located within the 5′ untranslated region of *SETDB2* that is capable of regulating the transcription of *SETDB2* and shows significant association with total serum IgE (66). Such situations are difficult to disentangle but highlight the potential for differing linkage disequilibrium patterns and/or allelic heterogeneity to manifest as inconsistent replication.

CANDIDATE GENES

The prohibitively high cost of genotyping combined with the paucity of available markers in the pre-genome era rendered high-resolution, hypothesis-free approaches impractical. As such, the vast majority of high-resolution studies were limited to individual genes whose candidacy was suggested by alternative, converging lines of evidence, including positional, mechanistic, and/or theoretical data. By design, this approach precluded identifying truly novel components of disease pathobiology, although it did instead provide a tool to ratify or refute existing candidates. The cost efficacy of the approach resulted in a large increase in the number of candidate gene association studies. However, these studies were invariably carried out in small, low-powered cohorts that are also prone to false positives, and consequently many of the results failed to replicate consistently between populations. This phenomenon is not limited to the context of asthma, but is widely recognized across a broad spectrum of complex traits (64, 69). For example, in 2002 a cross-trait analysis of candidate gene associations showed that less than 4% of associations studied three or more times were consistently replicated (64).

The design of genetic association studies is relatively simplistic. For categorical traits like disease status, allele frequencies at a small set of variants positioned in and around a gene of interest or the combinations thereof (haplotypes) are compared between cases and controls. These variants can take any format, such as insertion–deletion (indel) polymorphisms or single-nucleotide polymorphisms (SNPs). As of 2006, prior to publication of the first asthma genome-wide association study (GWAS), candidate gene studies had implicated more than 100 genes in the etiology of asthma (115). Of these, fewer than 10% had been replicated in more than 10 studies, even when the phenotype definition was expanded to include both asthma and atopy phenotypes and when the gene was considered the unit of replication, rather than individual variants or combinations thereof (115).

These relatively more promising asthma candidate genes included the prototypical type 2 cytokine genes *IL4* (interleukin 4) and *IL13* (interleukin 13) and the IL4 receptor gene *IL4RA* (now known as *IL4R*). Additionally, implicated in more than 10 studies was the beta-2 adrenergic receptor gene *ADRB2*, the candidacy of which has been supported by the efficacy of beta agonists in asthma and the gene's influence on beta-agonist responsiveness (100), and the positional candidate *ADAM33*. Other frequently replicated genes included the gene encoding the beta subunit of the high-affinity IgE receptor (*FCER1B*, now known as *MS4A2*), the proinflammatory cytokine gene *TNFA*, the surface antigen gene *CD14*, and the major histocompatibility locus genes *HLA-DRB1* and *HLA-DQB1*. That said, experimentally, some candidate genes have received considerably more attention than others, and factors such as publication bias, which influences the number of

Downloaded from www.annualreviews.org. Guest (guest) IP: 24.117.150.43 On: Tue, 14 Oct 2025 03:05:08

negative replications reported in the literature, further confound the direct interpretation of results. Unfortunately, large-scale meta-analyses capable of providing a clear synthesis of all available data are few and far between, not least owing to the diversity of the populations and environments studied. Furthermore, those that do exist often fail to detect a consistent overall effect, casting doubt on the credibility of many targets identified during the candidate gene era.

GENOME-WIDE ASSOCIATION STUDIES

GWASs leverage the high frequency of SNPs across the genome, as defined through sequencing, to enable the application of allelic association on a genome-wide scale. This technique is founded on the common disease–common variant principle, which predicts that the genetic architecture of common diseases is in large part composed of common, low-penetrance variants. Since GWASs are agnostic to what part(s) of the genome might be associated, they enable the detection of previously undescribed and unsuspected genetic components, assuming they are present in the population at an appreciable frequency. Variants detected as significantly associated in a GWAS are not necessarily themselves pathogenic, but may be in linkage disequilibrium with other, perhaps rarer, untyped variants that may be the source of the association.

The first GWAS of asthma was carried out in 2007 (109), and today, according to the publicly available GWAS Catalog (19), 38 loci, or genomic regions, have been associated with asthma per se at a p-value threshold of $p < 5 \times 10^{-8}$, the standard threshold commonly applied in GWASs (**Table 2**). This number markedly increases if intermediate phenotypes and disease subtypes are additionally considered. Among these 38 asthma-associated loci, the most consistently replicated, through GWAS and non-GWAS positional candidate gene studies and across a diverse range of ethnic backgrounds, is the cluster of genes on chromosome 17q12–21. This locus, originally brought to light in the first GWAS of asthma in 2007 (109), harbors sequence variants capable of regulating the expression level of several physically colocalized genes. These genes include *ORMDL3* (orosomucoid-like 3) (58, 90, 109), *GSDMB* (gasdermin B) (58), and *GSDMA* (gasdermin A) (60, 90). Variants that are capable of regulating the expression of local genes are referred to as *cis*-acting expression quantitative trait loci (eQTLs), and at least in the case of *ORMDL3*, they appear to have cell type–specific effects (89).

Large-scale studies powered to identify subgroup effects have further shown that the 17q12–21 signal is specific to childhood-onset disease. In addition, the relationship between genotype and disease appears to be moderated by early environmental exposures, including tobacco smoke (17), respiratory infection (130), and place of residence (132). The pathogenic mechanism or mechanisms that mediate these effects are as yet unclear. At least two of the genes positioned within the bounds of the asthma-associated 17q12–21 locus, however, appear to participate in similar processes underlying airway remodeling and responsiveness in asthma. Functional studies in mice show that *ORMDL3* expression affects airway remodeling (107), including airway smooth-muscle proliferation and contractility (21), with airway remodeling preceding airway inflammation. Similarly, transgenic mouse studies of *GSDMB* also suggest roles in airway remodeling and responsiveness but in the absence of lung inflammation (29). *ORMDL3*, an endoplasmic reticulum gene, mediates sphingolipid homeostasis and the unfolded protein (stress) response, while the function of *GSDMB* (also known as *GSDML*) is largely undescribed. In addition, there is growing evidence that expression of *ORMDL3* (or its mouse counterpart, *Ormdl3*) in the lung influences the host response to fungal (*Alternaria*) challenge (92) as well as the antiviral response to rhinovirus infection—showing a significant relationship with both viral load and the extent of airway inflammation (131). These data therefore suggest a mechanism for the interaction between genotype at the 17q12–21 locus and early respiratory infection in the development of asthma (130).

This table is collated from the publicly available GWAS Catalog (19), listing all GWAS hits for asthma per se (excluding intermediate or compound phenotypes) with a p value $< 5 \times 10^{-8}$ at the time of writing.

Downloaded from www.annualreviews.org. Guest (guest) IP: 24.117.150.43 On: Tue, 14 Oct 2025 03:05:08

Other loci achieving significant *p* values (i.e., below the genome-wide significance threshold of 5×10^{-8}) in multiple GWASs include a site on chromosome 2q12 in the vicinity of several interleukin receptor genes, namely *IL1RL1*, *IL1RL2*, and *IL18R1*. While these multigene loci are challenging to dissect, it is notable that *IL1RL1* encodes the receptor for IL33. The gene that encodes IL33 is separately implicated in the genetic etiology of asthma through a replicated locus on chromosome 9p24.1. IL33, a transcription factor and cytokine, is expressed in the airway epithelium, where it acts as a proinflammatory danger signal following its release from cells undergoing necrosis (resulting from infection or damage). Other widely observed sites of association include a region on 5q22.1 that contains the mitochondrial solute carrier gene *SLC25A46* and the hemopoietic cytokine gene *TSLP*, a complex region located within the major histocompatibility locus (6p21.32), the *C11orf30-LRRC32* site implicated elsewhere in an array of atopic traits (11q13.2), and the signal transducer and transcriptional modulator gene *SMAD3* (15q22.33).

A notable observation from GWASs of asthma is the profound lack of overlap between the results of early low-resolution linkage and positional cloning studies and those of subsequent high-resolution GWASs. Examination of the GWAS Catalog (19) shows that no marker positioned in or around the eight positionally cloned genes (**Table 1**) has yet achieved genome-wide significance for asthma, or even a more modest threshold of $p \leq 5 \times 10^{-6}$. Markers proximal to these genes do, however, achieve moderately low *p* values for a spectrum of alternative traits, including several of possible relevance to asthma. These traits include indices related to obesity (*DPP10*), inflammatory diseases of alternative epithelial surfaces (*HLA-G*), measures of lung function (*CYFIP2* and *NPSR1*), atopy (*HLA-G*), infection, and host–organism interactions (*DPP10* and *HLA-G*) (**Table 1**).

There are various explanations for this lack of overlap. Standard GWASs are not powered to capture linkage disequilibrium between typed variants and untyped variants of low minor allele frequency, while classic linkage studies are capable of detecting rare variants but require a larger effect size (high penetrance) to permit detection. Individual linkage signals may also reflect allelic and/or locus heterogeneity, with contrasting alleles or even genes underlying the signal in different pedigrees. These differences mean that the two approaches may target partially separable components of the genetic architecture and as such may account for an apparent lack of communality between the results of linkage studies and those of GWASs in asthma. However, the failure of GWASs to detect signals in regions implicated by linkage analysis may also suggest that the linkage represents a false positive, particularly when imputation of rarer untyped variants is included in the GWAS.

Asthma and Related Phenotypes

Epidemiological studies have shown that asthma commonly co-occurs at the level of the individual, or more broadly at the level of the immediate family unit, with a diverse spectrum of traits, from gastroesophageal reflux disease to obesity. These patterns of co-occurrence suggest a level of overlap in the underlying mechanisms of pathogenesis.

The atopic triad. Perhaps the most widely recognized pattern of co-occurrence is the one of asthma, atopic dermatitis (eczema), and allergic rhinitis (hay fever), which together are referred to as the atopic triad and characteristically present clinically in a temporal sequence known as the atopic march. Within this sequence, atopic dermatitis is typically the first component to manifest, with approximately 20–30% of individuals with mild disease and 70% of those with severe disease going on to develop asthma. Individuals who undergo this distinctive sequence of disease progression frequently exhibit a more severe and persistent phenotype, with increased risk of allergen sensitization.

Downloaded from www.annualreviews.org. Guest (guest) IP: 24.117.150.43 On: Tue, 14 Oct 2025 03:05:08

All three of the atopic triad traits are strongly heritable (asthma, 35–95%; allergic rhinitis, 33–91%; and atopic dermatitis, 71–84%) (116) and show patterns of familial aggregation. The traits demonstrate marked (though incomplete) genetic correlations, indicating the presence of both shared and unique genetic influences (asthma–atopic dermatitis, 0.35–0.55; asthma–allergic rhinitis, 0.47–0.90; allergic rhinitis–atopic dermatitis, 0.62–0.73) (86, 140). The molecular mechanisms for this multi-morbidity are unclear. Comparison of susceptibility loci revealed by early linkage studies and subsequent single-trait GWASs provided little evidence of overlap. Indeed, a greater level of coincidence was reported between atopic dermatitis and the Th1-driven skin disease psoriasis, although this was antagonistic in nature (mapping to shared genes but opposing alleles) (148). Similar instances of inverse (antagonistic) association have been documented across a variety of disease pairings, from chronic obstructive pulmonary disease and pulmonary fibrosis (65) to inflammatory bowel disease (IBD) and type 1 diabetes (146), suggesting the possible presence of balancing selection at these genetic sites. Pleiotropic effects, whereby a single locus influences two or more traits, have been widely reported for atopic dermatitis. A recent GWAS observed pervasive sharing of loci (121). Almost 78% of atopic dermatitis–associated loci identified were implicated in alternative immune-mediated traits, from IBD to psoriasis and multiple sclerosis. While none of these genome-wide significant loci matched established sites of association to asthma per se, the authors reported that a third of established asthma loci achieved nominal significance levels in atopic dermatitis with an equivalent direction of effect. This suggests the possibility of small effect sizes in asthma that require substantial levels of power for detection at a genome-wide significance level.

More recent attempts to deconstruct the molecular mechanisms of the atopic triad multimorbidity have adopted two main approaches. The first is in silico, involving data mining and the construction of protein-level functional interaction networks. This strategy has shown that atopic triad diseases share a larger fraction of proteins and a greater level of interconnectedness than would be expected by chance (2). Specifically, five proteins (IL4, IL13, IL1RL1, IL18R1, and TSLP) and two cellular pathways (involving GATA3-related and IL4 signaling) were identified as common to all three atopic triad traits. *GATA3* is a recognized regulator of T cell development, while *TSLP* encodes thymic stromal lymphopoietin, a hemopoietic cytokine that promotes Th2 immune responses. Together, these data highlight a common theme of the type 2 response.

The second approach has involved conducting cross-trait GWASs using compound atopic triad phenotypes. Marenholz et al. (97) examined infantile atopic dermatitis followed by childhood asthma and identified seven contributory loci: 1q21.3 (*FLG*), 5q31.1 (*IL5/KIF3A*), 6p12.3 (*EFHC1*), 11q13.1 (*AP5B1/OVOL1*), 11q13.5 (*C11orf30/LRRC32*), 12q21.3 (*SLC6A15/TMTC2*), and 17q21 (*IKZF3*). Subsequently, Ferreira et al. (46) extended this approach in a substantial collection of more than 360,000 individuals, seeking genetic risk factors shared among all three atopic triad traits. The authors identified 136 independent risk variants underlying this shared risk, more than a third of which mapped to novel loci. Only a small minority of variants (4.4%) showed stronger effects in one atopic trait relative to the remaining two. These included *GSDMB*, located in the major chromosome 17q12–21 asthma locus (with risk variants relatively more common in asthma), and *FLG*, the most significant and replicable site of genetic association with atopic dermatitis to date (more common in atopic dermatitis).

Filaggrin, encoded by *FLG*, forms a key structural component of the terminally differentiated epidermis. The gene contains a spectrum of loss-of-function mutations that associate with asthma occurring in conjunction with atopic dermatitis but not asthma occurring independently of atopic dermatitis (118). These data alongside an absence of *FLG* expression in the airway epithelia (excepting the hair-bearing outer nasal cavity) suggest that, in the subset of cases bearing *FLG* mutations, asthma may be a secondary to a compromised, "leaky" skin barrier that allows percutaneous transfer of allergens and pathogens. Consistent with this hypothesis, mice naturally deficient for filaggrin (the so-called flaky tail mutants) show increased levels of percutaneous allergen priming (43), and in humans, *FLG* mutations are additionally associated with increased rates of several Th2 phenotypes (such as food allergy) that manifest at sites anatomically remote to the epidermis (70).

Obesity. In addition to atopic traits, there is strong epidemiological evidence of an association between asthma and obesity, particularly in affluent countries. Obesity precedes the development of asthma, conferring a dose-dependent effect on asthma incidence (150). No consistent relationship, however, has been identified between excess weight and atopic status (125, 149), leading some to posit obese asthma as a separable disease phenotype (93). Proposed explanations for the epidemiological relationship between asthma and obesity include shared co-morbidities (such as gastroesophageal reflux disease) and/or shared pathological features (such as systemic inflammation, oxidative stress, or leptin resistance). The adipose-derived hormone leptin is a key metabolic signal and is typically observed at relatively increased levels in obesity. Leptin is associated with several immune functions and regulates airway diameter independently of inflammation (7), which is consistent with the relative inefficacy of anti-inflammatory agents in the treatment of obese asthma (122).

Asthma and obesity possess a modest genetic correlation of 0.29, accounting for approximately 8% of the total genetic component of obesity (59). The genetic underpinnings of this joint susceptibility are largely undefined, with a single exception: a common inversion on chromosome 16p11.2 (55) that affects the expression of a collection of genes participating in the regulation of energy balance and immunity. Analysis of GWAS signals relating to body mass index or asthma in asthmatics (a GWAS-informed candidate gene strategy) did not reveal any significant pattern of overlap (105). Likewise, attempts to map the shared genetic origins of asthma and obesity directly through GWASs have proven relatively unsuccessful. A GWAS of body mass index in 23,000 asthmatics yielded only limited evidence of a heterogeneous effect of *DENND1B* [an overall GWAS hit for asthma (129); see **Table 1**] in asthmatic children, an effect that could not be replicated outside of the discovery cohort (104). Equally, a GWAS designed to model the interaction between asthma and body mass index on a genome-wide scale identified no variants significant at a genome-wide threshold, although multiple variants in the classic asthma 17q21 locus were classified as suggestive (147).

Chronic obstructive pulmonary disease. Considering the adult age group, asthma can also overlap with chronic obstructive pulmonary disease (133). This disease is characterized by a progressive, refractory airflow limitation, typically associated with long-term tobacco smoke exposure. A genetic correlation of 0.38 is defined between chronic obstructive pulmonary disease and asthma (65). With the exception of the locus on chromosome 16p11.2, previously implicated in the joint susceptibility to asthma and obesity (55), GWASs have not yet revealed shared sites of association between asthma and chronic obstructive pulmonary disease (65).

Inflammatory bowel disease. Several parallels can be drawn between asthma and IBD. IBD encompasses two major clinical entities: Crohn's disease and ulcerative colitis. Both IBD and asthma represent chronic relapsing inflammatory phenotypes that affect mucosal epithelial surfaces, albeit remotely from one another (in the gastrointestinal and respiratory tracts, respectively). The diseases additionally share several risk factors. As with asthma, a lack of breastfeeding is associated with an increased risk of IBD, as is early exposure to antibiotics. Furthermore, there is now accumulating evidence of an elevated prevalence of asthma (and atopic dermatitis) in IBD, with a

Downloaded from www.annualreviews.org. Guest (guest) IP: 24.117.150.43 On: Tue, 14 Oct 2025 03:05:08

diagnosis of asthma associated with significantly increased odds of early- and late-onset ulcerative colitis as well as Crohn's disease (76). Familial clustering of IBD is consistent with a genetic component, with pooled twin studies indicating a heritability of 0.75 for Crohn's disease and 0.67 for ulcerative colitis (56). While the genetic correlation between asthma and IBD is not, to the best of our knowledge, currently defined, evidence supporting the presence of genetic overlap dates back to early linkage studies (26).

More recent attempts to map the genetic determinants of IBD (IBD overall or its two major clinical entities separately) through GWASs confirmed genetic intersection between these traits, identifying at least 11 sites of association ($p < 5 \times 10^{-8}$) coincident with those described by asthma GWASs: chromosomes 1q25.1 (*TNFSF18* and *TNFSF4*) (13, 49, 72), 1q31.3 (*DENND1B* and *CRB1*) (32, 49, 72, 87), 2q12 (*IL18R1*, *IL1RL1*, and *IL1RL2*) (32, 49, 72, 87), 3q28 (*LPP*) (32), 5q31 (*NDFIP1*) (32, 49, 72, 87), 6p21.32 (*PBX2*, *NOTCH4*, *C6orf10*, *BTNL2*, *HLA-DRA*, *HLA-DRB5*, *HLA-DQA1*, and *HLA-DQA2*) (5, 8, 32, 47–49, 72–74, 77, 87, 102, 128, 138, 155, 158, 159), 6p21.33 (*HLA-C* and *MICA*) (32, 72, 73), 6q15 (*BACH2*) (32, 49, 72, 87), 11q13.5 (*C11orf30*) (5, 13, 32, 49, 72, 87), 15q22.33 (*SMAD3*) (32, 49, 72, 87), and 17q12–21 (*GRB7*, *IKZF3*, *ZPBP2*, *GSDMB*, *ORMDL3*, and *GSDMA*) (5, 13, 32, 49, 72, 87, 102) (**Table 2**). Among these sites, the 17q12–21 locus has received considerable research attention because it is the most significantly associated locus for asthma; shows replicable association with ulcerative colitis, Crohn's disease, and IBD overall; and coincides with the most significant Crohn's disease–associated eQTL (13). Other loci of interest include *SMAD3*, which encodes SMAD family member 3, a signal and transcriptional modulator that is responsive to transforming growth factor β (TGF-β) and is therefore key to the TGF-β-mediated epithelial-to-mesenchymal transition and fibrosis. Similarly, *BACH2* (BTB domain and CNC homolog 2) encodes a transcription factor essential for T and B lymphocyte differentiation. *C11orf30* encodes the nuclear protein EMSY, which has postulated roles in epithelial immunity, growth, and/or differentiation (41). *C11orf30* has also been implicated in a range of atopy-related traits, from polysensitization to atopic dermatitis, eosinophilic esophagitis, and total serum IgE. Together, these data indicate substantial levels of genetic communality between IBD and asthma and direct emphasis toward the mucosal immune barrier in these diseases.

Asthma and Infection

A role of early severe viral respiratory infections in the development and exacerbation of asthma in children is widely recognized, particularly with regard to the respiratory pathogens rhinovirus and respiratory syncytial virus (52). Both of these viruses are early predictors of recurrent wheezing, with early rhinovirus-related wheeze predictive of subsequent asthma (88). The mechanism for this phenomenon, however, is poorly defined. Evidence of host genetic factors in respiratory tract infectious diseases is controversial, marred by issues of bias and confounding (120). A recent meta-analysis of 386 studies targeting infectious diseases of the respiratory tract nonetheless highlighted a role for the *IL4-TLR2-CCL2* axis, with *IL4* sequence variants achieving significance in a pooled model, indicating shared host effects common to multiple respiratory infections (120). Notably, sequence variants proximal to *IL4* have previously been implicated in the etiology of asthma through candidate gene association studies (see above). Mice deficient for *IL4* show increased susceptibility to some respiratory pathogens as well as increased mortality (110), consistent with the gene's role in host–pathogen dynamics. A direction of focus onto the mucosal barrier arising from GWASs adds weight to the rationale for investigating viral and other microbial infections in asthma and underscores the importance of ensuring that such data are captured efficiently at the time of study population collection.

EPIGENOME-WIDE ASSOCIATION STUDIES

The term epigenetics describes changes in gene activity and/or function that do not involve alteration of the DNA sequence. DNA methylation was the first epigenetic change to be widely studied, following the observation that CpG methylation is associated with gene silencing and the patterning of gene expression that determines cellular types and functions (33). CpG sites represent positions in the DNA sequence in which a cytosine nucleotide and a guanine nucleotide are separated by a single phosphate group when read in the 5′-to-3′ direction (5′-C-p-G-3′). CpG islands encompass broader regions of DNA that contain a relative enrichment of CpG sites. Epigenetic investigations also include modifications of the histones and other regulatory elements that bind to DNA [exemplified in the Encyclopedia of DNA Elements (ENCODE) project].

While the original coinage of the term epigenetics implied epigenetic inheritance (e.g., at loci showing genomic imprinting), the vast majority of epigenetic modifications are not heritable. In general, epigenetic alterations can be considered responses to environmental influences, providing exposure-dependent plasticity in gene activity or function. Although epigenetically modified genes and pathways may be central to disease pathobiology, they are likely to represent changes in gene regulation in response to environmental or other factors and are not causal of disease susceptibility in the same way as true genetic variants.

Further factors that should be considered in interpreting epigenome-wide association studies (EWASs) are the distinctive epigenetic patterns of particular cell types and the cellular heterogeneity present in peripheral blood and different tissues (84). In contrast to genetic studies, where polymorphisms are a constant feature of DNA derived from any tissue of the human body, epigenetic modifications contain strong cell-specific signatures. Consequently, for example, peripheral-blood leukocytes may not contain core epigenetic events that are present in asthmatic airways or eczematous skin.

While it has been suggested that generalized abnormalities of methylation may be present in asthma (12), the hypothesis has subsequently not gained support. Well-powered EWASs that have controlled for cellular heterogeneity have, however, generated some consistent and interesting results that indicate the importance of particular pathways and cell types in the etiology of atopic asthma.

Epigenetic Features of Asthma: Outside of the Lung

In 2015, Liang et al. (85) surveyed epigenetic associations between serum IgE concentrations and methylation at loci concentrated in CpG islands in 95 nuclear pedigrees, using a first-generation Illumina methylation array to test DNA from peripheral-blood leukocytes. They validated positive results in additional families and a general population sample. Replicated associations (false discovery rate $<10^{-4}$) were found between IgE and low methylation at 36 loci. Many genes annotated to these loci encode known eosinophil products (in particular *IL5RA*, encoding the eotaxin receptor), whereas other associations implicated phospholipid inflammatory mediators (such as the one encoded by *LPCAT2*), specific transcription factors, and mitochondrial proteins (such as the one encoded by *L2HGDH*).

Modeling of the association with differential white cell counts showed that 10% of the variation in IgE level was attributable to eosinophil counts and that the top three loci (indicating the level of eosinophil activation) accounted for a further 13% of IgE variation. The authors confirmed eosinophil activation by showing that methylation in isolated eosinophils differed significantly in subjects with and without asthma and high IgE levels.

Downloaded from www.annualreviews.org. Guest (guest) IP: 24.117.150.43 On: Tue, 14 Oct 2025 03:05:08

A subsequent study of approximately 1,000 children from the Avon Longitudinal Study of Parents and Children assessed associations of asthma and wheeze with DNA methylation at 450,000 sites (using an Illumina methylation array), extending the tests for differentially methylated regions beyond CpG islands. Samples were taken at 7.5 and 16.5 years of age (6). The authors identified 302 CpGs associated with current asthma status (false discovery rate–adjusted p value $<$ 0.05) and 445 associated with current wheeze status at 7.5 years, with substantial overlap between the two. Genes annotated to the 302 associated CpGs were related to IL4 production and eosinophil migration. As with the adult EWAS (85), the associations were attenuated when adjusted for eosinophil and neutrophil cell count estimates. At 16.5 years, two sites, mapping to the *AP2A2* and *IL5RA* genes, remained associated with current asthma after adjustment for cell counts.

Epigenome-wide DNA methylation was most recently investigated in the whole-blood DNA of asthma cases and controls at ages 4–8 years from four European birth cohorts within the Mechanisms of the Development of Allergy project (153). Cell type specificity was addressed in eosinophils and nasal epithelial cells. Consistently lower methylation levels were observed at 14 loci that showed genome-wide significance in meta-analyses; all of the loci were associated across childhood from ages 4 to 16 years but not at birth. All 14 CpGs were significantly associated with asthma in a replication study using whole-blood DNA and were strongly associated with asthma in purified eosinophils. Whole-blood transcriptional signatures associated with these CpGs indicated increased activation of eosinophils, effector/memory CD8-T, and natural killer cells and reduced naive T cells. Of the 14 CpGs, 5 were associated with asthma in respiratory epithelial cells, indicating cross-tissue epigenetic effects. These CpGs and their associated transcriptional profiles suggest activation of eosinophils and cytotoxic T cells in childhood asthma, consistent with early-life microbial exposures.

A smaller study of methylation in cord blood (36) found that methylation in *SMAD3* was selectively increased in asthmatic children of asthmatic mothers and was associated with childhood asthma risk. As highlighted above, GWASs of asthma have found *SMAD3* to be important, and further analyses may be necessary to separate the epigenetic changes from the effects of heritable polymorphism.

EWAS association between genome-wide DNA methylation in whole-blood cells and total IgE levels has been examined in two panels of Hispanic children (22). The results confirmed many associations with total IgE levels previously reported in Caucasians. As with other investigations, adjustment for whole-blood cell types resulted in markedly fewer significant sites. Top novel findings from an adjusted meta-analysis were in the genes *ZFPM1* ($p = 1.5 \times 10^{-12}$), *ACOT7* ($p = 2.5 \times 10^{-11}$), and *MND1* ($p = 1.4 \times 10^{-9}$).

Overall, the above EWASs have identified consistent sets of markers that show activated eosinophils to be of particular importance in childhood asthma and adult asthma when accompanied by a high serum IgE level. Eosinophils develop in the bone marrow and are activated and recruited into tissues in response to stimuli that include IL5 and eotaxin (126). IL5 and its specific receptor subunit, IL5RA, are therapeutic targets for asthma, and these epigenetic findings validate drugs that include benralizumab (which binds to IL5RA) and the humanized IL5-specific antibodies mepolizumab and reslizumab. These biologics are very expensive (on the order of US$30,000 per patient each year), and as such, assays for measuring the level of activation of IL5RA may become of value in predicting which patients will respond to treatment. Alternatively, the *LPCAT2* gene, implicated by Liang et al. (85), may define a way to treat asthma with small-molecule antagonists that will prevent the stimulus-dependent formation of the potent proinflammatory lipid mediator platelet-activating factor (PAF) (127).

Epigenetic Features of Asthma: Within the Lung

A study of the epigenome in primary airway epithelial cells from 74 asthmatic and 41 non-asthmatic adults (111) revealed a regulatory locus on chromosome 17q12–21 (the same locus identified by asthma GWASs) associated with asthma risk and epigenetic signatures of specific asthma endotypes. *ORMDL3* expression was related to the differentially methylated region at this locus, while the expression of *GSDMB* was not. A differentially methylated region near *CCL26* (encoding eotaxin 3) also had a significantly associated eQTL. This important study reminds us that asthma is primarily a disease of the airways, whereas effects in peripheral-blood leukocytes reflect changes in the circulating immune system. This may explain why the peripheral-blood leukocyte studies outlined above primarily reported strong associations with the total serum IgE, with relatively weak findings for asthma itself. Despite the technical challenges of obtaining samples from within the lung, further genomic and methylation studies of the airway epithelium appear necessary to enable the field to move forward.

TRANSCRIPTOMICS

The development of array-based and, subsequently, RNA sequencing technologies has fostered high-throughput transcriptomic analyses of asthma across a host of cell populations, time frames, and exposure conditions.

Transcriptomics as a Tool for Defining the Impact of Disease on a Tissue or Cell System

In one of the first large-scale, genome-wide gene expression studies of asthma, Dixon et al. (38) characterized the transcriptomes of peripheral-blood leukocyte–derived lymphoblastoid cell lines of children with and without asthma and examined the relationship between transcript abundance and genotype. Clear patterns of heritability were observed, with more than 15,000 transcripts demonstrating a narrow-sense (h_2) heritability greater than 0.3, including both local and distal effects and clear patterns of enrichment for specific biological processes. Nonetheless, only 10 transcripts showed significant disease-related differences in abundance, and none of these retained significance following adjustment for multiple comparisons. This result is perhaps unsurprising given the context in which disease-related differences in gene expression were sought—i.e., unchallenged, immortalized cultured cell lines. Nevertheless, the authors were able to confirm that asthma-associated markers in the 17q23 region account for 29.5% of variance in *ORMDL3* expression, supporting *ORMDL3* as a major candidate gene in this region.

Transcriptional signatures of asthma have since been sought in a variety of minimally invasive disease-relevant tissues, ranging from sputum (157) to whole blood (16, 27) and bronchial brushings (91). Peripheral-blood data sets suggest the presence of replicable transcriptomic signatures relating to the extent of asthma control, with the strongest and most highly reproducible enriched gene sets expressed by specific immune cell lineages, including 11 eosinophil-specific gene sets (suggesting parallels with EWAS data) (27). Whole-blood results also indicate variation in gene expression by disease severity, with a substantially greater magnitude of differential expression documented between healthy subjects and severe asthmatics than between healthy subjects and those with mild or moderate disease. However, similar gene sets have been reported as affected in both comparisons, suggesting a disease-severity-related transcriptomic continuum (16). That said, in their 2016 analysis of the Unbiased Biomarkers in Prediction of Respiratory Disease Outcomes (U-BIOPRED) cohorts, Bigler et al. (16) showed that the number of differentially expressed genes

Downloaded from www.annualreviews.org. Guest (guest) IP: 24.117.150.43 On: Tue, 14 Oct 2025 03:05:08

in whole blood was dramatically cut (by as much as 90%) when blood cell counts were included as covariates, suggesting that the majority of differential expression may be accounted for by disease-related changes in peripheral-blood composition.

Shifting the compartment of study from peripheral blood to the epithelial barrier, in 2017 Loffredo et al. (91) performed a comparative analysis of publicly available transcriptomic data sets of asthma from bronchial epithelial cells. The authors identified a consensus signature of 159 core genes differentially expressed by disease status with a consistency in directionality across the majority of studies (five of the eight studies analyzed). Functional pathway analysis of these genes revealed a close-knit interaction network, with key features highlighting themes of epithelial–mesenchymal imbalance, remodeling, and dedifferentiation. Traditional markers of epithelial-to-mesenchymal transition were notably absent; instead, *EFNB2*, *FGFR1*, *FGFR2*, *INSR*, *IRS2*, *NOTCH2* (participating in ephrin, insulin, and Notch signaling), *NTRK2*, and *TLE1* were identified as central components of the interaction network. Key genes were differentially expressed across the full spectrum of disease severity and showed progression along the disease-severity gradient. Moreover, similar gene expression patterns could be approximated in organotypic air–liquid interface culture conditions via insulin depletion. These gene expression data support a hypothesis of barrier dysfunction in asthma and suggest the possibility that this dysfunction may be secondary to systemic factors (such as insulin insufficiency or resistance).

Transcriptomics as a Tool for Pathway or Candidate Gene Exploration

We have highlighted above that transcriptomics offers an unbiased method of characterizing pathways and their composite transcripts perturbed in the context of asthma, as well as cross-tissue and inter-subgroup comparisons. In addition, however, transcriptomics offers a valuable opportunity to catalog the impact of experimentally manipulated endogenous or exogenous factors on a cellular system, or to simply track gene expression patterns through key developmental stages or processes. Widely applied experimental manipulations include controlled knockdown of a single candidate gene, exposure to a known risk factor (e.g., microbial stimuli or organic or nonorganic airborne particulates), or a combination of the two.

By way of example, the process of class-switch recombination from IgA/IgG/IgM to IgE is of central importance to atopic diseases such as asthma, since it is required for B cells to express IgE. In 2016, Zhang et al. (161) monitored global gene expression and exon retention during the activation of immunoglobulin class switching in human B cells. The authors identified a complex yet organized transcriptional cascade accompanying the process of class-switch recombination, including genes known to participate in the moderation of circadian rhythms (*BHLHE40* and *NFIL3*). The involvement of clock genes is notable since circadian oscillations represent a prominent feature of asthma symptoms (39), and experimental deletion of an alternative clock gene (*BMAL1*) recently revealed links between the circadian clock and both viral airway pathology and asthma phenotypes (40).

The role of viral respiratory infection in asthma is a major area of emerging interest (see the section titled Asthma and Infection). To this end, Etemadi et al. (42) recently profiled the transcriptional response to rhinovirus infection in human alveolar epithelial cells. These data, derived from a controlled in vitro system, revealed a substantial impact of rhinovirus infection on global gene transcription, with distinct functional categories showing enrichment at the various stages of the infection time course, including an early inflammatory chemokine response. The most strikingly upregulated gene across all time points was the transcriptional regulator gene *EGR1* (early growth response 1), implicated elsewhere in the transcriptional response to smoke exposure in the nasal mucosa (99).

Downloaded from www.annualreviews.org. Guest (guest) IP: 24.117.150.43 On: Tue, 14 Oct 2025 03:05:08

Considering the process of lung development, Melén et al. (106) queried publicly available gene expression data sets that had assayed gene expression in the developing human or murine lung, and sought overlap with known asthma candidate genes. Candidate genes were not significantly overrepresented among developmentally regulated genes, but a small minority of candidates did demonstrate differential expression and consistent temporal trends in both mice and humans. These included *NOD1*, *EDN1*, and *CCL5*, as well as the positionally cloned *HLA-G* and *RORA* genes, both of which have more recently been identified to be of importance by asthma GWASs. These data cumulatively add context to existing associations and suggest possible roles in lung development or morphogenesis.

THE LUNG MICROBIOME

It has long been hypothesized that microbiotas play a key role in the etiology of asthma and, more broadly, atopic disease. The prevalence of asthma has increased dramatically over recent decades in parallel with a decline in the rates of infectious disease. These changes accompany improvements in sanitation, cleanliness, and vaccination. Small family sizes, birth by caesarian section, and urban living all represent risk factors for asthma, while early farm exposures and breastfeeding confer protective effects. Such observations have been assimilated into the hygiene hypothesis, first set out in 1989 (136), positing that reduced early microbial exposure and its impacts on immunity underlie the post–Industrial Revolution atopy and asthma epidemic. Responsible for a transformation in our understanding of microbial factors in asthma has been a revolution of a different kind. Only approximately 5% of bacteria can be cultured in the laboratory through standard techniques—the so-called great plate count anomaly (135). By contrast, next-generation sequencing approaches, which make use of the balance between sequence conservation and variation in the bacterial 16S rRNA gene, enable the isolation and accurate identification of most microorganisms. The technique has been successfully applied to the upper and lower airways as well as the gut and has provided novel insights into the role(s) played by bacteria in asthma.

Historically, the lung was considered a sterile landscape. Application of culture-independent techniques has, however, shown that neither the upper nor the lower airways can be considered sterile in either health or disease (asthma, chronic obstructive pulmonary disease, or idiopathic pulmonary fibrosis) (reviewed in 95). Moreover, accumulating evidence suggests that colonization of some anatomical sites may even precede birth, being initiated in utero (1, 23). In health, microbiotas detected in the lung demonstrate considerable overlap with those seen in the upper airways (14, 98), arguably consistent with microaspiration as a source of lung microbiotas. In disease, the overlap between the upper airways and lung is less clear (37, 61).

Culture-independent microbiome profiling specifically in asthma has revealed significant differences between cases and controls in the lower airways, in particular with regard to members of the gram-negative phylum Proteobacteria (54, 61). Interestingly, *Haemophilus parainfluenzae*, also a member of the Proteobacteria phylum, appears to promote blunt corticosteroid responses through activation of the TAK1/MAPK pathways, suggesting a possible microbial mechanism for corticosteroid resistance in asthma (54). While a role for Proteobacteria in asthma is contentious, data from murine models also highlight weak inflammatory properties of airway commensals (accounting for their tolerance), while asthma-associated Proteobacteria trigger lung inflammation and associated pathology (79).

CONCLUSIONS: A GENOMIC VIEW OF ASTHMA

The field of asthma genetics has changed dramatically over the last decade. Technological advancements have brought with them the tools with which to interrogate the human genome,

Downloaded from www.annualreviews.org. Guest (guest) IP: 24.117.150.43 On: Tue, 14 Oct 2025 03:05:08

epigenome, and transcriptome, as well as the microbial flora of humans, with unprecedented accuracy and volume. This toolbox has facilitated the stepwise accrual of information regarding the pathogenic mechanisms of asthma, free from hypothesis or bias, and enabled direct comparison between diseases. The challenge now is twofold: first, generating a meaningful synthesis of these data, which are both substantial and diverse, and second, explaining the considerable proportion of asthma heritability that remains unaccounted for despite the volume of existing data—challenges that are closely interwoven.

At the time of writing, GWASs alone have yielded at least 38 genomic loci that show association with asthma with p values that meet or exceed the widely applied genome-wide threshold for significance of 5×10^{-8}. These loci show little to no correspondence with the eight previously positionally cloned asthma susceptibility genes, and likewise, historical candidate genes do not feature prominently in asthma GWAS results. The explanation for this lack of intersection may in part be statistical, reflecting the presence of false positives among reported susceptibility genes. This is not, however, the only possible explanation; also likely to be influential are a disparity in the types of effects that are amenable to capture by the techniques of linkage and association (including the potential role of rare variants) and the overarching role of unmeasured variation. The latter encompasses the phenotype itself, the underlying genetic architecture, and salient environmental exposures.

Epidemiological data have clearly demonstrated the relevance of a broad spectrum of environmental factors in the etiology of asthma, from tobacco smoke exposure to early respiratory infection and birth by caesarian section. More recent analyses of the lung microbiome in asthma have built on these observations, indicating a dysbiosis in disease and controversially highlighting a significant role for Proteobacteria. The participation of environmental factors in the etiology of asthma renders gene × environment interaction a plausible explanation for inconsistent replication between cohorts. Indeed, analyses of the major asthma locus on chromosome 17q12–21 have revealed evidence of interplay with several exogenous factors, including early respiratory infection (130) and early passive environmental tobacco smoke (17), the latter of which has been independently replicated (141). Since narrow-sense heritability estimates may be inflated by the presence of nonadditive effects (96), gene × environment interactions may plausibly contribute to the issue of apparent missing heritability. Today, gene × environment interactions are being modeled on a genome-wide scale through GWASs (143), but the success of such approaches will be tied to the selection and precise measurement of pertinent environmental exposures, the collection of information regarding their temporal sequence, and the generation of sufficient statistical power. Clarification of the relevant environmental influences in asthma may therefore be warranted, enabling more straightforward identification and replication of environmentally malleable genetic effects.

A second observation from the genetic studies of asthma has been the genetic correlation between asthma and a range of other phenotypes, and thence the accompanying overlap in susceptibility genes or variants. Analyses of this overlap have already afforded some insights into shared mechanisms, e.g., pointing to the mucosal immune barrier in IBD and the type 2 response in atopic triad diseases. Indeed, in some cases, such as the epidermal barrier gene *FLG*, association with asthma appears to occur only within the context of a second trait (in the case of *FLG* atopic dermatitis). Such observations underscore the importance of patient stratification and clear phenotype definition in study design and lend weight to the notion that asthma is both genetically and clinically heterogeneous. Unfortunately, in the majority of cases, the effect size conferred by any given risk variant is relatively low, limiting their individual utility for distinguishing patients in a clinical setting. Nevertheless, these variants and their patterns of pleiotropy provide valuable information on the mechanisms of disease causation and co-morbidity. Unlike the cancer field

Downloaded from www.annualreviews.org. Guest (guest) IP: 24.117.150.43 On: Tue, 14 Oct 2025 03:05:08

(notably breast cancer), the field of asthma remains at some distance from personalized medicine, but it appears likely that at least a subset of genes that affect asthma susceptibility also influence risk for other disease traits. Furthermore, transcriptomic data suggest that blood-based transcriptional signatures exhibit relationships with features of asthma itself, such as disease severity or control.

Transcriptomic screening provides a systematic technique for assessing the impact of a single gene (through experimental up- or downregulation) on a cellular system, and this will be key to understanding the roles of asthma susceptibility genes defined to date. Such techniques are already widely applied for cataloging the transcriptional underpinnings of disease-relevant processes, be it class-switch recombination in B cells or response to infection in alveolar epithelial cells. Moving toward a more complete understanding of the genetic basis of asthma will require characterizing the role(s) of established susceptibility genes through these and other similar techniques, as well as focusing on patient stratification and characterization of environmental influences.

Genomics of Atrial Fibrillation

Alejandra Gutierrez, MD[b] and **Mina K. Chung, MD**[a]

[a]Department of Cardiovascular Medicine, Cleveland Clinic, Cleveland, OH; Department of Molecular Cardiology, Cleveland Clinic, Cleveland, OH

[b]Department of Internal Medicine, Cleveland Clinic, Cleveland, OH

Abstract

Atrial fibrillation (AF) is a common clinical arrhythmia that appears to be highly heritable, despite representing a complex interplay of several disease processes that generally do not manifest until later in life. In this manuscript we will review the genetic basis of this complex trait established through studies of familial AF, linkage and candidate gene studies of common AF, genome wide association studies (GWAS) of common AF, and transcriptomic studies of AF. Since AF is associated with a five-fold increase in the risk of stroke, we also review the intersection of common genetic factors associated with both of these conditions. Similarly, we highlight the intersection of common genetic markers associated with some risk factors for AF, such as hypertension and obesity, and AF. Lastly, we describe a paradigm where genetic factors predispose to the risk of AF, but which may require additional stress and trigger factors in older age to allow for the clinical manifestation of AF.

Keywords

Atrial Fibrillation; Genomics; Stroke; Hypertension

Introduction

Atrial fibrillation (AF) is the most common sustained arrhythmia seen in clinical practice. The etiology of AF is multifactorial, but includes a genetic predisposition to the arrhythmia. The road towards discovering the genetic basis of AF has progressed from identification of genes associated with familial AF, to clinical observational studies demonstrating hereditability of common AF, to genome wide association studies (GWAS) that have identified to date 14 genetic loci associated with AF (Table 1)[1–16]. However, identification of risk loci is only the start of a long process to discover the mechanisms by which these variants increase AF risk. Moreover, despite the identification of inherent

genetic risk, we do not fully understand why AF typically does not manifest until later decades of life, nor why certain clinical factors, such as hypertension, obesity, male sex, or Caucasian ancestry, predispose to AF. Here, we will review the published evidence for the genetic basis of AF and discuss the results of recent genomic and transcriptomic analyses that may yield insights into some clinical observations of AF incidence.

Heritability of Atrial Fibrillation

The lifetime risk for developing AF is one in four for people older than 40 years [17]. Traditional risk factors for AF include older age, obesity, alcohol consumption, hypertension, left ventricular hypertrophy, heart failure, prolonged PR interval and coronary artery disease [18]. The prevalence of AF has increased as a result of the aging and increased prevalence of obesity in the general population and in response to an increased awareness and diagnosis of the arrhythmia [18].

Despite the complex and aging-related clinical risk factors for the disease, AF is heritable. In the Framingham study parental AF increased the risk of AF in offspring [19]. The odds ratio was 1.85 for AF in offspring who had one parent with AF and 3.23 when the sample was restricted to patients with parents who developed AF when they were <75years old. A more recent study involving the Framingham cohort reported that new onset AF occurred more frequently in subjects with compared to without familial AF (adjusted hazard ratio 1.40; 95% CI 1.13–1.74), independent of traditional AF risk factors [20]. In Iceland, Arnar et al. studied 5269 patients diagnosed with AF and age- and sex-matched controls[1]. The relative risk of AF in first degree relative pairs was 1.77. When the analysis was restricted to first degree relatives of patients with early onset AF (diagnosed <60 years of age), relative risk of AF was 4.67. Ellinor and colleagues reported that lone AF (i.e. AF in the absence of structural heart disease) greatly increases the risk of AF in family members. A family history of AF was found in 38% of patients with lone AF; the relative risk for sons was 8.1, daughters 9.5, brothers 70, and sisters 34[21]. Lastly, a Danish twin study reported 22.0% concordance rates for monozygotic pairs compared to 11.6% for dizygotic pairs ($p<0.0001$) with heritability of AF estimated to be 62%[22]. Of note, such twin studies are of particular interest because they are less likely to lead to inflated estimates of heritability as a consequence of shared environmental risk factors.

Familial Monogenic AF

Families exhibiting a very high prevalence of AF have been reported as early as 1936 [23–25]. Traditional approaches to identifying genes responsible for AF in these presumably monogenic (or Mendelian) forms of AF include linkage studies and candidate gene searches. These studies have identified several ion channel gene mutations that were associated with familial AF, including potassium channel mutations (e.g. in *KCNQ1, KCNE2, KCNH2, KCNJ2, KCNA5*) for which gain-of-function mutations might be expected to promote AF by shortening of action potential duration and effective refractory periods, as well as in the sodium channel mutations (in *SCN5A* and *SCN4B*), which have also been associated with dilated cardiomyopathy[26–35].

Author Manuscript

Author Manuscript

Author Manuscript

Several non-ion channel genes have also been associated with familial monogenic AF, including *PRKAG2*, associated with familial Wolff-Parkinson-White syndrome and AF[36], and *NPPA*, which encodes for atrial natriuretic peptide [37]. Further, some developmental genes have been implicated, including genes encoding transcription factors involved in cardiogenesis from the *GATA* family[38–40] and *NKX2-5*, a homeobox-containing transcription factor involved in cardiac development and septation with mutations associated with atrial septal defect and AV conduction abnormalities [41]. Structural genes have also been associated with familial AF, including *GJA5*, which encodes for connexin 40 [42], a gap junction protein that is expressed in the atria and the conduction system and that is crucial for action potential propagation through myocytes, and *RYR2*, a gene which encodes the ryanodine receptor responsible for releasing intracellular stores of calcium [43, 44]. Finally, genes encoding nuclear membrane associated proteins have been linked to familial AF. These include *LMNA*, which encodes for lamin expressed in the inner nuclear lamina. Mutations in *LMNA* have also been associated with muscular dystrophy, dilated cardiomyopathy, risk of sudden cardiac death[2, 45], and progeria syndrome. *NUP155* has also been associated with AF[46, 47]. This gene encodes for a nucleoporin that is involved in the assembly and functioning of the nuclear pore complex that regulates transport of macromolecules across the nuclear envelope between the cytoplasm and the nucleus [46, 47].

Polygenic Non-familial Common AF

Genetic Architecture

Although familial AF studies have contributed much to our understanding of the genes associated with monogenic forms of AF, they represent only a small fraction of the overall burden of disease. Overall, the genetics of common AF pathogenesis is complex, involving modest contributions to the risk of disease from genetic variations in many genes. The genetic architecture of a disease depends on the number of variants that influence a given pathology, the effect size of each variant on the phenotype, and the frequency of the variant. Complex diseases such as AF follow the "common disease common variant" hypothesis of genetic architecture where common variants with small effects appear to be responsible for a majority of the heritability of the trait[48].

Linkage and Candidate Gene Studies

Initial strategies to identify polymorphisms predisposing to common polygenic AF included linkage analyses and candidate gene based association studies. Linkage analyses attempted to apply the same analytic techniques used to identify monogenic forms of disease to common polygenic forms of disease but proved to be inadequately powered to detect the modest effects of polymorphisms contributing to the risk of common AF [49].

Failed linkage studies were followed by candidate gene association studies, which relied on prior knowledge to generate hypotheses about possible polymorphisms that could have a causal relationship with a given disease and were limited by the potential bias of studying only what is already known [50]. Since these studies concentrated on only a small region of the genome, their pretest probability of identifying a real signal was low. The data published

was further influenced by publication bias. A meta-analysis of 370 studies reporting on 36 different genetic associations illustrated this point well. The study found that in 25 of 36 cases, the first study overestimated the replicated effect[49]. Further, 39% of the genetic associations studied had significant heterogeneity between results [49]. Lack of replication for candidate gene association studies is common and can be a result of differences in study design, differences in studied populations with variable allele frequencies or relative risks of a certain variant, or due to real biological differences[50]. Furthermore, the polygenic nature of common and complex diseases involving many variants with small relative risks resulted in many studies being substantially underpowered leading to a high rate of false positive reports [49].

While as a whole candidate gene association studies have been disappointing, such studies nevertheless yielded some valuable insights into the potential mechanisms leading to AF. To begin, such studies implicated ion channel genes as contributants to risk of common AF, including those identified in familial studies. Potassium channel genes, including *KCNQ1, KCNH2, KCNJ5, KCNJ8, KCND3* and *KCNE 1* through *5* have been associated with AF risk[13, 51–57]. The *KCNE* genes encode the beta subunits of voltage gated channels; *KCNE1* and *KCNQ1* contribute to the I_{Ks} current [52–54, 58]. Gain of function of I_{Ks} [52, 59] results in a faster repolarizing current and shorter effective refractory period, increasing the excitability of cells and susceptibility to arrhythmia. Loss of function prolongs the action potential and increases the likelihood of early after depolarizations [60]. *KCNA5* encodes for the α-subunit of the voltage sensor of a channel that generates the ultra-rapid potassium current, I_{Kur}, which is abundant in atria and detectable in failing ventricles. Hayashi et al. found a novel gain of function variant and a previously described *KCNA5* loss of function variant in a cohort of 72 patients with lone AF [13, 61].

Mutations in sodium channel subunit genes have also been associated with AF. The voltage gated sodium channel consists of a pore forming α subunit, encoded by the *SCNA* genes, and 4 different β subunits encoded by *SCN1B-4B*. This channel is responsible for the rapid influx of sodium ions that underlies the upstroke (phase 0) of the cardiac action potential. Several variants of *SCNA5*, which encodes the cardiac α-subunit of Nav1.5, have been reported in patients with common polygenic AF [62]. Gain of function mutations decrease the threshold voltage for the action potential and increase cellular excitability[63]. β-subunits modulate the gating and voltage dependence of the channels, impact the trafficking of sodium channel to and from the cell membrane, and aid in cell adhesion. Mutations in the four β-subunits have been reported to attenuate sodium currents and shift the voltage-dependence of sodium channel gating [64, 65]. A single nucleotide polymorphism (SNP) in *SCN10A*, which encodes Nav1.8, a voltage gated sodium channel that participates in the late sodium current, was recently described to be associated with early onset AF [66].

Candidate gene analyses have also identified polymorphisms in non-ion channel genes with familial AF. Implicated genes include those encoding connexin 40, *GJA5* [7, 67–69], the transcription factor gene *NKX2.5*[70, 71], and the *LMNA* gene[72]. Genes involved in the renin-angiotensin-aldosterone pathway, including the angiotensin converting enzyme, angiotensin gene promoter and angiotensinogen[73–76], have also been associated with AF.

Identification of AF-associated Genetic Loci Through Genome Wide Association Studies

Genome wide association studies (GWAS) represent a relatively new but important study design to overcome the inherent bias of candidate gene analyses. By comparing the frequencies of common genetic variants among subjects with and without a disease or level of quantitative trait, GWAS has been able to identify hundreds of novel genetic associations over the last 10 years involving common single nucleotide polymorphisms (SNPs). GWAS analyze hundreds of thousands to millions of SNPs concurrently. To correct for multiple testing, thresholds for significance typically need to be adjusted to a p value of $< 5\times10^{-8}$, which effectively corrects for 1 million independent tests. Once a SNP or a set of SNPs in a region reaches genome wide significance, the next important step is to link the SNP association to a causal gene. Generally, this process begins with an assessment of the genes that are in proximity or within the susceptibility locus and should not be deemed certain until a functional mechanism has been fully worked out in detail through multiple additional experiments[77].

Developmental Genes

In 2007, the first GWAS for AF identified a susceptibility locus at chromosome 4q25 in a population of European descent and replicated this association in an Asian population [12]. This association has been further replicated in all AF GWAS to date[78–80]. Further, this locus was associated with recurrence of AF after ablation and new onset AF in the postoperative period after coronary bypass surgery [3, 78].

Additional GWAS have identified at least 4 independent loci at chromosome 4q25 for AF [81]. As is often the case, the lead SNPs in this region are in non-coding regions. Nevertheless, the closest gene is the paired-like homeodomain 2 *PITX2* gene, located in a linkage disequilibrium (LD) block upstream to the susceptibility locus. *PITX2* is involved in embryogenesis and left-right differentiation of the heart. *PITX2* encodes 3 different isoforms of the protein by alternative splicing. Importantly, the Pitx2c isoform is mainly found in the left atrium and pulmonary veins [82][83]. In Pitx2c conditional knockout mice, Pitx2c-deficient mice do not develop a pulmonary myocardial sleeve, and Pitx2 appears to suppress a left atrial sinus node program [84]. Compared to wild type mice, Pitx2null+/− and Pitx2null−/− mice heterozygous and homozygous for a Pitx2-null allele that removes all Pitx2 isoform function showed step-wise increased expression of *HCN4*, which encodes a hyperpolarization-activated cyclic nucleotide-gated channel contributing to pacemaker currents, as well as *TBX*3 and *SHOX2* that are also required for sinoatrial node development[83]. Expression of *KCNQ1* was also increased[84], which would result in a shorter effective refractory period, facilitating action potential triggering and conduction. Mouse *PITX2* conditional or heterozgygote mutation models have shown alterations in ion channel, calcium handling, gap and tight junction gene expression[85–88], *PITX2* regulation of miRNAs[87–89], and atrial arrhythmia inducibility [84, 85, 87]. Thus, *PITX2* is a biologically attractive candidate causative gene in the region, as it appears to be involved in the regulation of several ion channel genes that plausibly may predispose to atrial arrhythmia, it directs asymmetric morphogenesis of the heart, is involved in the formation of

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

pulmonary veins, the putative site of AF initiation targeted by clinical AF ablation [90], and appears to repress a left atrial sinus node program, genetic variation of which might contribute to electrical triggers recorded within pulmonary vein ostia.

The expression of *PITX2* has been shown to markedly decrease postnatally. The mechanisms leading to postnatal inactivation of *PITX2* are actively being researched and include possible mediation by various risk factors, such as pressure and volume overload and oxidative stress that come with age. Tao, et al, showed that postnatal inactivation of *PITX2* leads to abnormal R-R intervals and to differential expression of genes involved in cell junction organization, including the intercalated disk, ion channels and caveolae. [91]

GWAS of AF have also identified several other loci associated with transcription factors that appear to be important for cardiac development. One of these is located on chromosome 16q22 intronic to the zinc finger homeobox 3 gene (*ZFHX3*), known as AT motif-binding transcription factor 1(*ATBF1*) [4], which is involved in regulation of growth and differentiation of skeletal muscle and neuronal tissues [4]. *ZFHX3* is required for the transcriptional activation of the gene POU class I homebox 1 (*POU1F1*), which interacts with *PITX2*, enabling DNA binding and transcriptional activity. This might be a mechanism by which it predisposes to AF [80]. Later, another GWAS described *PRRX1* which encodes for a homeodomain transcription factor expressed in connective tissue in the developing heart[10]. In animal models, knockout of *PRRX1* led to abnormalities in the pulmonary vasculature [92].

Ion Channels and Pores

Thus far, two loci in ion channel genes have been significantly associated with AF in GWAS studies. First, a locus was identified on 1q22 within an intron of the *KCNN3* gene, which encodes for the calcium activated potassium channel SK3 [11]. SK3 contributes to the repolarization phase of the action potential[93]. Second, a locus on chromosome 15q24 within an intron of the hyperpolarization-activated cyclic nucleotide-gated 4 (*HCN4*) gene was described [10]. *HCN4* is expressed in the sinoatrial (SA) node and underlies the I_f current normally responsible for the pacemaker current in nodal myocytes. Mutations of this channel may lead to diminished action potential frequency (heart rate slowing) and delayed after depolarizations that might trigger AF [94]. As discussed above, Pitx2 represses Hcn4 expression in the left atrium[84][83].

Structural Genes

A meta-analysis of GWAS in 2010 identified several new AF loci, including three in/near genes involved in cellular structural components. Cell membranes contain invaginations, known as caveolae, that participate in cell transport. A locus on chromosome 7q31 within an intron of the gene *CAV1*, which encodes caveolin-1, was associated with AF[10]. *CAV1* is co-expressed with a potassium channel gene (*KCNH2*), which is involved in the repolarization phase of the action potential. The risk allele and AF are associated with decreased expression of *CAV1*[95]. Further caveolin-1 has been postulated as an anti-fibrotic element in atrial tissue, since down-regulation of Cav-1 by siRNA leads to increased TGF-β1-induced activation of the Smad signal pathway and collagen production[96].

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

An intronic SNP located on chromosome 14q23 in the gene *SYNE2*, which encodes for nesprin-2, has also been associated with AF. Nesprin-2 is located in the outer nuclear membrane and sarcomere and anchors nuclei to the cytoskeleton. A large meta-analysis of GWAS by Ellinor, et al, identified a susceptibility locus between two genes, *SYNPO2L* and *MYOZ1*, on chromosome 10 and another locus in the an open reading frame on chromosome 9 (*C9orf3*) [10]. Myozenin-1 is a protein involved in stabilizing the sarcomere, encoded by *MYOZ1*. *C9orf3* region is associated with three coding genes, including *FBP1* and *FBP2*, which are involved in gluconeogenesis[10].

Gene mRNA Expression studies

Although GWAS studies identify regions in the genome that are associated with a phenotype, the lead SNP within a susceptibility locus is often not the causal variant. Furthermore, the lead SNP is often not within a coding region of a gene and usually near several genes, making it challenging to determine which gene in the region is the causal gene. One way to identify with more certainty the causal gene is to leverage gene expression studies to determine whether a lead SNP is preferentially associated with the level of mRNA of one or more genes nearby. SNPs that are associated with mRNA are often termed expression quantitative trait loci (eQTLs) [97]. As the control of gene expression is often tissue-specific, assessment of relationships between SNPs and mRNA expression among circulating cells in blood may be inadequate to assess the effects of SNPs on the expression of genes predisposing to AF. Gene expression studies involving more relevant target tissues, such as the left atrium itself, may substantially increase the yield of identifying causal genes among susceptibility loci of AF.

Genetic variants can change the expression of mRNA and proteins by *cis* or *trans* mechanisms. *Cis*-acting variants affect expression of genes nearby on the same chromosome as the gene variants, while *trans*-acting variants can act on genes that are far from them. Such transcriptional studies can help guide the identification of the genes associated with genetic variants identified by GWAS.

eQTL analysis of the AF-associated locus in between *SYNPO2L* and *MYOZ1* has demonstrated an association between the high risk alleles in this region and decreased expression of *MYOZ1*, implicating *MYOZ1* as the most likely causal gene associated with this AF locus [95, 98]. In another eQTL study predominantly involving right atrial appendage tissues, AF risk alleles were associated with increased expression of *PITX2a* and decreased expression of *MYOZ1, CAV1, C9orf3*, and *FANCC* [95].

Despite the finding of cis-eQTLs for genes noted above, significant eQTLs for the top GWAS locus from AF on chromosome 4q25 were not found for *PITX2c* in human adult left atrial appendage tissues [99]. Recently, we performed RNA sequencing on human left/right atrial tissue pairs and reported the presence of an intergenic long non-coding RNA sequence adjacent to the *PITX2* gene (PANCR) differentially expressed in the left atria and eye but no other heart chambers. Expression of PANCR RNA correlated with *PITX2c* mRNA expression. In human embryonic stem cells, both PANCR and *PITX2c* RNAs were coordinately expressed during early differentiation of the stem cells towards

Author Manuscript

Author Manuscript

Author Manuscript

Author Manuscript

cardiomyocytes. siRNA-mediated PANCR knockdown decreased *PITX2c* expression and resulted in similar RNA expression profiles as *PITX2c* knockdown cells, whereas *PITX2c* knockdown did not affect PANCR expression, suggesting that PANCR is an important regulator of *PITX2c* expression [100]. However, similar to *PITX2c* in human adult left atrial appendage tissue, chromosome 4q25 risk SNPs for AF were not associated with PANCR or *PITX2c* expression[99, 100]. These findings may be a consequence of *PITX2* and PANCR being most active during embryologic development in the left atrium or in the tissue within the pulmonary vein – left atrial junction which may have some distinct differences with the tissue making up the adult left atrial appendage.

A combination of large scale GWAS, cis-eQTL and functional evaluation led to the identification of 5 novel loci associated with AF near the genes *NEURL, GJA1, TBX5, CAND2* and *CUX2*[15]. AF-associated cis-eQTLs were identified for *CAND2, GJA1*, and *TBX5*. *NEURL* encodes for an E3 ubiquitin ligase that was found to co-localize with *PITX2*. Another signal was found in a SNP intronic to *TBX5*, a transcription factor implicated in conduction abnormalities, and in *CAND2* [15], which encodes for a TATA binding protein transcription factor involved in myogenesis[101]. eQTL analysis of *CAND2* and *TBX5* showed that the risk alleles were associated with an increased expression of these genes. Additional functional studies demonstrated that *NEURL* and *CAND2* knockout zebrafish models had longer atrial action potential duration[15]. Propagation of the action potential through myocytes requires a balanced expression of two gap junction proteins: connexin 40 and 43 [102]. Cis-eQTL associations showed the AF risk allele at the *GJA1* locus was associated with lower expression of *GJA1*, which encodes connexin 43. [15] Connexin abnormalities can lead to reduced conduction velocity and action potential propagation. In the same paper, a novel SNP located within an intron of the *CUX2* gene was found to be associated with AF only in a Japanese population [15]. *CUX2* was recently associated with increased oxidative DNA damage in embryonic neurons [103]. However, a significant cis-eQTL was not identified for the risk allele.

Transcriptomic Analyses and the Age Paradox in AF

Despite the association of several developmental genes with AF risk, AF typically does not manifest until decades after birth. To gain insight on this paradox, we recently performed a gene expression study of left atrial appendage tissue from 207 adults with AF and 32 adults without AF to compare gene expression in 3 groups based on AF history and rhythm at the time of resection of the atrial appendage: 1) No AF history and in sinus rhythm (SR/SR); 2) AF history and in sinus rhythm (AF/SR); and 3) AF history and in AF rhythm (AF/AF)[9]. We identified differentially coexpressed gene modules between the SR/SR and AF/SR groups (“AF susceptibility” comparison), and between the AF/SR and AF/AF groups (“AF activity or persistence” comparison). Gene set enrichment analyses showed that AF susceptibility was associated with decreased transcriptional responses to cellular stress, inflammation, oxidation, and unfolded proteins, while AF persistence was associated with changes in ion channel expression and decreased stress responses. These findings may help explain the AF age paradox, whereby AF does not manifest until there is impaired responsiveness to persistent cellular stress and aging, decades after the GWAS-identified AF loci exert their activity during cardiac and pulmonary vein development.

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

The reduced cellular stress response to protein unfolding is of particular interest, as this geneset includes targets of several transcription factors such as the CREB/ATF family, HSF1, ATF6, SRF, E2F1, and SP1[9]. Alterations in many of these transcription factors can lead to abnormal proteostasis and deposition of unfolded amyloid proteins. Deposition of isolated atrial amyloid is well described and associated with older age and the presence of AF [104, 105]. Interestingly, atrial amyloid has also been reported to be more frequent in left than in right atrial appendages [105]. Isolated atrial amyloid protein has been shown to be due to aggregates of atrial natriuretic peptide (ANP) [104, 106], and expression levels of *NPPA*, which encodes for ANP, are high in adult human atrial appendage tissues. Expression of *NPPA* was up-regulated in Pitx2 heterozygote and null mice [83]. Further, a recent study in a Chinese population suggested that *TBX5* mutations increases the expression of ANP and connexin 40[107]. Senile accumulation of the protein aggregates may contribute to the predisposition to AF with aging.

AF Genetics and Stroke

One of the most devastating complications of AF is stroke. Conventional risk factors account for only 60% of the variation in the risk of stroke [108]. Similar to AF, stroke has a genetic predisposition. Further, risk factors differ depending on the etiology of the stroke, which includes hemorrhagic, ischemic, cardioembolic, large artery due to atherosclerosis, small vessel and cryptogenic forms[109]. Genetic studies have attempted to elucidate new stroke prediction, prevention and treatment approaches and have led to the discovery of common genetic variants associated with both AF and stroke (Table 2, Figure 1).

Soon after publication of the first GWAS of AF implicating SNPs in the 4q25 region, the same SNPs were also identified as risk factors for ischemic stroke. Gretarsdottir, et al, showed that rs2200733, one of the first 4q25 SNPs demonstrated to be strongly associated with AF risk, was associated with ischemic stroke, and even more strongly with cardioembolic stroke [110]. This association was further replicated in a targeted sequencing study of a Polish population[111]. Lastly, another study showed a different locus in the same region was associated only with cardioembolic stroke [112].

Large scale studies have found similar genetic associations between AF and stroke. Gudbjartsson, et al, reported a case control genomic study, finding that the SNP rs7193343 at the *ZFHX3* locus was associated with ischemic and cardioembolic stroke[113]. Several GWAS studies have confirmed this association, including the METASTROKE study, which incorporated about 70,000 subjects. These studies confirmed that the *PITX2* and *ZFHX3* SNPs were associated with ischemic stroke and more specifically with cardioembolic stroke, even though only half of their population was sub classified by type of stroke [114]. A recent exome sequencing study replicated the *ZFHX3* locus association with ischemic stroke[115]. Using the METASTROKE collaboration data, an association between ischemic stroke with an AF-risk SNP intronic to *CUX2* was found, though the AF risk allele was paradoxically associated with a decreased the risk of stroke (OR 0.95.; 95% CI 0.91–0.98). Sub-analysis by type of stroke found an association of *GJA1* and *TBX5* AF-risk SNPs with cardioembolic stroke[15].

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

The mentioned associations are likely due to an enrichment of AF cases among ischemic and cardioembolic stroke cases. They might be markers of AF as a predominant cause of embolic rather than non-embolic stroke. Studies have not consistently classified strokes and the lack of differentiation by subtype of stroke reduces power for stroke subtype analyses. Without a large study of isolated cardioembolic stroke, signals attributed to ischemic stroke are an aggregate of multiple mechanisms leading to stroke. Nevertheless, these genetic variants might ultimately prove useful in differentiating the etiology of an ischemic stroke and in identifying patients with cryptogenic stroke who are most likely to have underlying undiagnosed AF. These patients may warrant more monitoring and potential anticoagulation for secondary prevention of stroke.

Current stroke prevention scores rely on clinical data to determine therapy, but adding genetic markers may improve the predictive value of these tools. Tada, et al, constructed a 12 SNP genetic risk score (including SNPs near *PITX2, KCNN3, PRRX1, CAV1*, C9orf3, *SYNPO2L, SYNE2, HCN4*, *ZFHX3*) to identify people at higher risk for AF and found that the score in addition to the CHADS2 score led to better prediction of ischemic stroke in AF patients[116]. The renin angiotensin aldosterone (RAAS) system plays an important role in inflammation, hypertension, tissue remodeling and fibrosis. A preliminary association of the G6 polymorphism (a polymorphism located in the promoter region of the angiotensin gene leading to increased angiotensinogen production) has been found in stroke in two candidate gene studies [118, 119] and in one candidate gene study of AF patients [76]. Tsai, et al, showed that the addition of the G6 polymorphism to the CHADS2 score improved the ability to predict stroke in an AF population[117]. Other elements of the RAAS system, such as the angiotensinogen gene and angiotensinogen converting enzyme gene, have also been associated with AF and stroke in candidate gene analyses [74, 75, 120, 121].

Inflammation likely plays a role in both stroke and AF. Ischemic brain injury is characterized by inflammation. However, data regarding a polymorphism in the CRP gene, which has been reported in candidate gene analysis as an independent risk factor for stroke, have been conflicting [122, 123]. Other components of the inflammatory cascade studied include IL-1a, TNFα, IL-10, ICAM-1, though evidence has again been inconsistent [124–128] with studies limited by heterogeneity and small sample size.

Risk factors for AF: Hypertension, Obesity and Common Genetic Variants

Hypertension is an important modifiable risk factor for AF [129]. While GWAS for hypertension have not identified common SNPs that have also been associated with AF, several genetic variants associated with hypertension may contribute to AF. The genetic architecture of blood pressure appears to be extremely complex with ~100 independent variants accounting for only around 2% of the variance in blood pressure [130]. These include loci near *NPPA* and *NPPB*, which encode precursors of the natriuretic peptides. Polymorphisms in these loci correlate with the level of circulating natriuretic peptide and blood pressure [130, 131]. AF has been associated with variants in the *NPPA* gene [132, 133], causing resistance to ANP breakdown and increasing its half-life [37]. Atrial amyloid is largely derived from ANP. Transcriptomic differential gene expression analysis (discussed above) showed that AF susceptibility is associated with decreased targets of cellular stress

response to protein unfolding [9], leading to abnormal proteostasis and deposition of unfolded amyloid protein.

Several genes involved in the RAAS, including those for the angiotensin converting enzyme, angiotensin and angiotensin receptor, have been associated with essential hypertension by candidate gene analysis[134–136]. Some studies of patients with essential hypertension have identified RAAS gene variants that are related to increased risk of AF [73, 76, 137]. Polymorphisms in this system have also been linked to stroke. However, the RAAS system is involved in multiple pathologies and attributing some variants to certain disease states might be challenging in the setting of so many confounders. Nevertheless, the possibility that some variants contribute to multiple pathologies through pleiotropy seems plausible, as AF, obesity, hypertension are highly intertwined conditions and such pleiotropy has been well documented in other settings (Figure 1).

Other clinical risk factors for AF that have been associated with common genetic variants include obesity and the metabolic syndrome. Obesity increases the risk of atrial fibrillation by almost 50%[138]. In a GWAS meta-analysis of waist-hip ratio, *TBX15* was associated with increased waist-hip ratio. Unlike the other SNP hits in this study, *TBX15* did not differ by gender[139]. Candidate gene studies have shown that *CAV1* polymorphisms resulting in decreased expression of the gene are associated with insulin resistance and the metabolic syndrome in Hispanic and Caucasian cohorts[140, 141].

Conclusions

Genomic analyses have provided important insights into the pathogenesis of AF, though much still remains unknown. While GWAS have identified common genetic variants associated with AF, identification of the causative genetic variants and their functional mechanisms remains challenging. For example, the top replicated AF-associated locus on chromosome 4q25 is in an intergenic region, but the functional variants and the direct mechanisms by which these variants increase AF susceptibility is still poorly understood. The nearest gene, *PITX2*, is a biologically attractive candidate causative gene, as it directs asymmetric morphogenesis of the heart, is involved in the formation of pulmonary veins, and represses a left atrial sinus node program that might contribute to pulmonary vein triggers. However, the connections between the AF-associated SNPs and gene expression or function of *PITX2* remain elusive. Transcriptional studies in atrial tissue have made connections between SNPs and genes in several other AF risk loci, including for *MYOZ1, CAV1, C9orf3*, *CAND2, GJA1*, and *TBX5.* Analyses also suggest that the delay in AF manifestation until later in life may be associated with impaired transcriptional responses to cellular stress. Future GWAS of AF with much larger sample sizes will undoubtedly increase the number of susceptibility loci that are significantly associated with AF risk. Further studies are needed to determine functional mechanisms by which these genetic loci contribute to AF risk, stroke, and/or other common co-morbid conditions. Understanding these mechanisms will set the stage for the development of new therapeutic agents that target the causative genes.

ABSTRACT Over the past decade, genomic characterization of *Bordetella pertussis* isolates recovered from US pertussis patients has unveiled noteworthy structural gene order variations. Whole-genome sequencing (WGS) shows that although *B. pertussis* exhibits little gene sequence variation, genomes from clinical isolates frequently differ in gene order through rearrangement between insertion sequence elements. To better understand rates of genome rearrangement and single nucleotide polymorphism (SNP) in *B. pertussis*, intra-patient genomic diversity was examined. Five states submitted, on average, five isolates per patient specimen following culture confirmation to the US Centers for Disease Control and Prevention for molecular characterization. Analysis of 149 patient specimen sets revealed only rare SNP variation, while isolate sets from 12 patients included genomic rearrangements that did not impact vaccine antigen production. To investigate the frequency and stability of such rearrangements during laboratory culture, replicate cultures of two pairs of isolates differing by duplication and inversion were subcultured for eight serial passages. WGS confirmed the initial presence of rare duplication mutations that became dominant in later passages, as well as the stable maintenance of a large, inverted genomic region during passage. These findings suggest that *B. pertussis* exhibits genomic diversity within a single clinical diagnostic specimen and acquires genomic variations during serial laboratory passages, indicative of bacterial genomic plasticity. Importantly, these rearrangements did not impact the frequency or distribution of SNPs. These results underscore the importance of minimizing the laboratory passaging of clinical isolates used for infectious disease surveillance.

IMPORTANCE The whooping cough-causing bacterium *Bordetella pertussis* can alter its genetic structure while conserving areas essential for vaccine efficacy. By examining *B. pertussis* from infected patients, we demonstrate the significance of reducing laboratory manipulation of bacteria to maintain reliable monitoring data from laboratory cultures. Public health officials can use these data to develop efficient disease control tactics and better understand *B. pertussis*'s adaptability. This study highlights the importance of immunizations and the necessity of thorough genetic surveillance in the fight against this chronic and avoidable respiratory illness.

KEYWORDS *Bordetella pertussis*, genomic rearrangements, genomic variations, genetic polymorphisms, whole genome sequencing, genome typing, serial passage, pulsed-field gel electrophoresis, genome assembly, genome duplication

Pertussis (whooping cough), a debilitating respiratory disease caused by the bacterium *Bordetella pertussis*, remains a frequently reported vaccine-preventable disease worldwide. Beginning in the 1990s, acellular pertussis (aP) vaccine formulations containing pertussis toxin (Pt), filamentous hemagglutinin (Fha), and pertactin (Prn), with

or without fimbriae types 2 and 3 (Fim2/3), replaced whole-cell pertussis (wP) vaccines in many industrialized countries. Following the switch, an increased incidence of pertussis was reported in the USA and elsewhere (1–3) until the start of the coronavirus disease 2019 pandemic (4) despite widespread vaccination coverage (5). Multiple factors likely explain the resurgence of pertussis cases, including more rapidly waning immunity conferred by aP vaccination compared to wP vaccine formulations (5, 6), as well as improvements in diagnostic testing and reporting (7).

The bacterium appears to have changed following the switch to aP vaccine formulations. Specifically, the emergence of new alleles *ptxP3, prn2,* and *fim3B,* as well as frequent gene disruption causing Prn deficiency (8–16), has been suggested to be adaptive responses to aP vaccine-induced immune pressure. Despite these mutations, traditional molecular typing methods have described *B. pertussis* as genetically monomorphic due to the paucity of single nucleotide polymorphisms (SNPs) among clinical isolates (17, 18). Somewhat paradoxically, pulsed-field gel electrophoresis (PFGE) often revealed additional diversity, including among clinical isolates within epidemics, though the underlying mutations causing such variations remained unverified (19–23).

Through recent advances in whole-genome sequencing (WGS), long-read technology allowed profound sequence-based characterization of circulating *B. pertussis*. Indeed, the alignment of several complete genome assemblies from clinical isolates revealed that current circulating isolates exhibit considerable diversity of gene order arrangements, both compared to laboratory reference strains and each other (24, 25). These gene order differences appeared as large duplications and inversions facilitated by insertion sequence (IS) elements, notably IS*481* (24, 25). However, these studies have been limited to characterizing genetic differences between representative, single colonies from multiple patients (8, 21, 25–29), and little is known about the frequency or stability of genomic rearrangements during infection of human hosts or laboratory culture.

The current study combined traditional molecular typing and WGS to examine the frequency of *B. pertussis* genetic variation in infected patients at the single time point of diagnosis. It also examined the impact of subsequent laboratory subculturing on genome stability. The findings presented in this study demonstrate *B. pertussis* genomic rearrangement plasticity during growth in infected patients and laboratory culture. Therefore, limiting laboratory passage during genomic characterization is crucial for accurate genomic surveillance.

RESULTS

High nucleotide sequence conservation among replicate isolates from individual patients

The current study analyzed 705 isolates of *B. pertussis* recovered in sets of 2 to 10 colonies per patient during culture confirmation of positive nasopharyngeal specimens from 149 patients (Fig. 1A and B; Table S1). Sequence variation within the bacterial population infecting individual patients was evaluated by comparing genome-wide SNP profiles between isolates in each patient set and summarized using the maximum pairwise SNP distance observed between isolates in the set. As anticipated, the observed number of SNPs within sets was relatively low. Among the 149 patient isolate sets, 115 (77%) exhibited no SNPs, 16 (11%) displayed one to three SNP differences, and only 18 (12%) presented more than three SNPs within sets (Fig. 1C). This observation of high genetic similarity within patients aligns with the current understanding of nucleotide sequence conservation among circulating *B. pertussis* (18, 30).

Chromosome rearrangements detected among replicate isolates from individual patients

Genetic variation among isolates in each set was investigated through PFGE and WGS. First, PFGE profiles of the 705 isolates studied (Table S2) revealed that sets from 12 patients exhibited variation, observable as the appearance of additional bands (Fig. 2A)

Downloaded from https://journals.asm.org/journal/msystems on 15 October 2025 by 24.117.150.43.

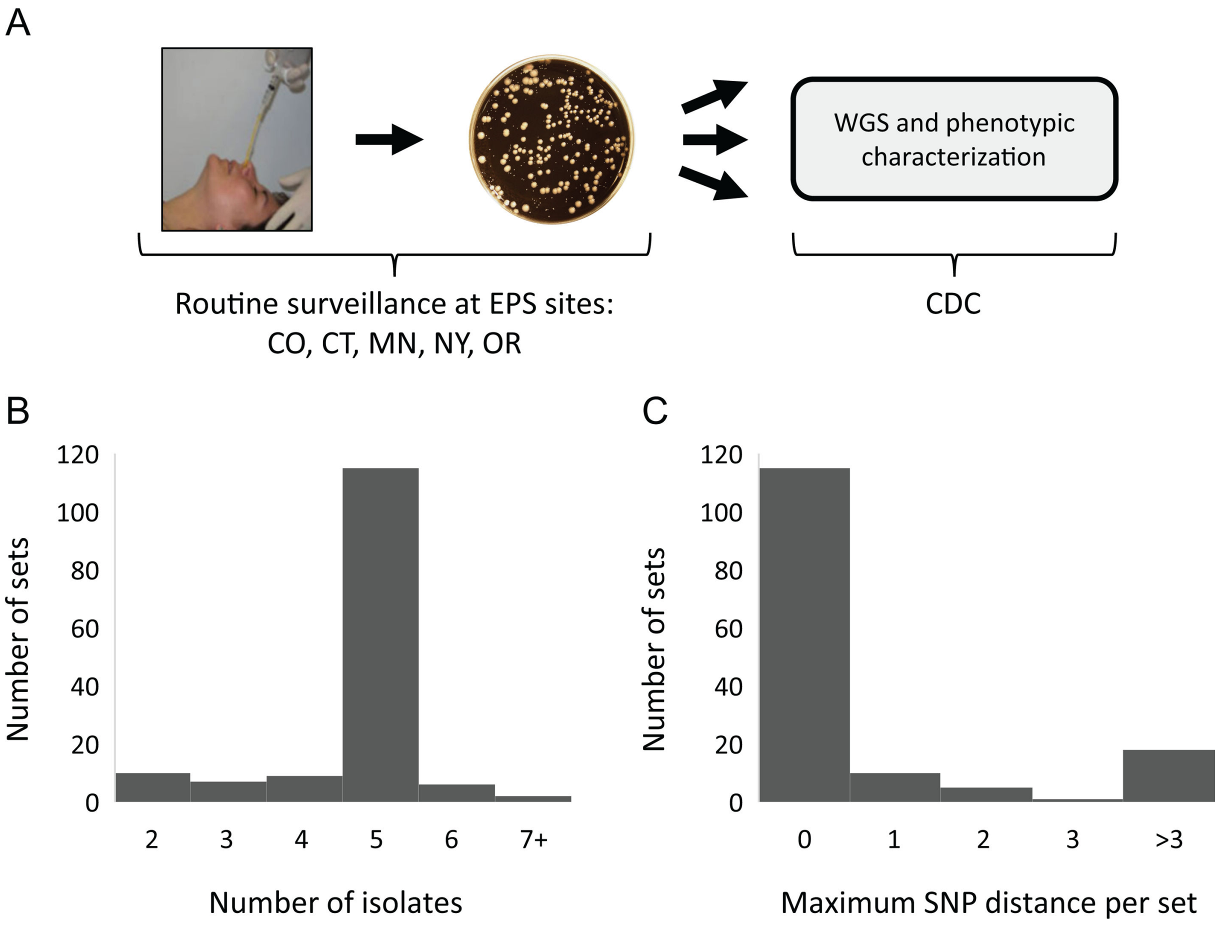

FIG 1 Genome sequence variation among isolates from the same patient. (A) Specimen collection and processing (image courtesy of CDC Public Health Image Library). (B) Histogram depicting the number of isolates per set. Eighty-nine percent of sets included at least four isolates. (C) Rare SNPs within isolate sets from 149 patients analyzed. Seventy-seven percent of sets had zero SNP differences within sets; 11% of sets had one to three SNP differences; and only 12% had more than three SNPs within sets. Reported values represent maximum pairwise SNP distances.

or reshuffling of bands (Fig. 2C) in profiles of one or two isolates that differed from others in those patient sets. Short-read and long-read sequencing platforms provided additional resolution to investigate potential chromosomal variations captured by the PFGE profile differences among select isolates in patient sets (11, 15, 19, 20, 32, 68, 73, 75, 93, 113, 131, 150). Whole-genome alignment of complete *de novo* assemblies was used to identify evidence of large chromosomal rearrangements, such as duplications, inversions, or translocations (Fig. S1A, B and S2). Such alignments revealed inversion differences in seven patient sets. For example, in patient set 20 (Table S2), genomes of isolates J817 and J818 exhibited structure CDC300, while J816, J819, and J820 had structure CDC237 (Fig. 2C). Structures CDC237 and CDC300, named according to their associated PFGE profiles, differ by a single large inverted genomic segment of approximately 1 Mbp (Fig. 2D), as described in previous studies (25, 26).

In a similar manner, mapping short Illumina reads to a reference genome was used to investigate potential duplications, observable as localized increases in coverage depth in five patient sets at distinct genomic regions (Fig. S1A). For instance, sequencing reads from three isolates in patient set 15 (J763, J764, J765) exhibited even coverage across the 4.1 Mbp reference genome. However, reads from J766 and J767 of that same patient set 15 each yielded regional increases in sequencing coverage at positions 1.69–1.96 Mbp and 775–855 kbp, respectively (Fig. 2B). The observed coverage peak in J767 corresponded to approximately twice the genome-wide average, suggesting the 80 kbp region was now present in two copies, similar to duplication events previously observed in

Downloaded from https://journals.asm.org/journal/msystems on 15 October 2025 by 24.117.150.43.

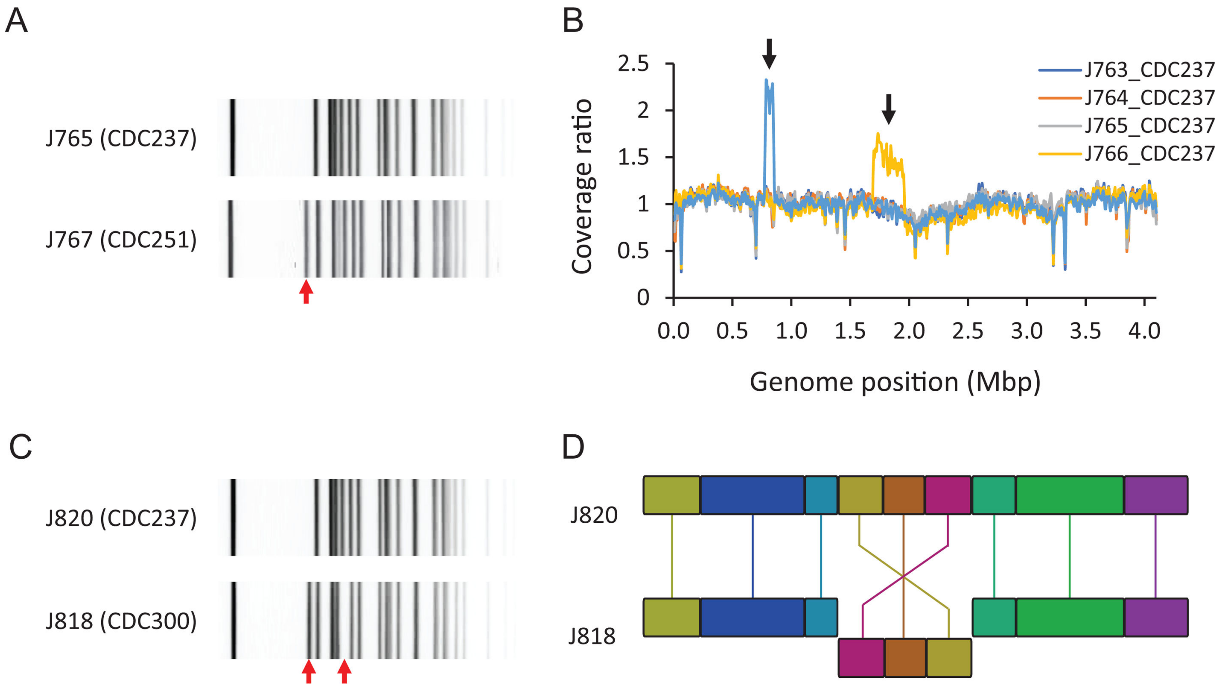

FIG 2 Genome variations among isolates from the same patient. (A) The PFGE profile of J767 contained an additional band (bottom and red arrow) that differentiated it from the profile of CDC237 and the rest of that patient's set (J763, J764, J765, and J766). (B) WGS identified the variation in J767 as a regional duplication (blue arrow). An increase in coverage is also observed with J766 (yellow arrow) but did not reach 2× coverage. (C) The banding pattern of the PFGE profiles of a patient set from CO differed by two bands (bottom and red arrows), consistent with CDC structures 237 and 300. (D) WGS identified the variation detected in panel C as a regional genomic inversion. In panel B, genome coordinates are indicated in the *x*-axis; the *y*-axis indicates the number of times each position on the genome coordinate is observed.

other studies (24). By contrast, the observed coverage peak in J766 did not reach 2× the genome average. Furthermore, PacBio long-read sequencing and assembly confirmed duplication of the genomic region corresponding to the coverage peak in J767 but not J766.

Stability of genomic inversions and emergence of duplications during laboratory passage

To assess the frequency and stability of the genetic differences observed within patient sets, genomic DNA was sequenced from serial laboratory passages at multiple intermediate timepoints. Two representative isolate pairs, J766/J767 from patient set 15 and J818/J820 from patient set 20, were selected based on their within-set genomic variation of duplication and inversion, respectively. Five replicate lineages of each were maintained on Regan-Lowe charcoal agar without cephalexin for eight serial passages. To track duplications, shotgun Illumina sequencing reads of passages 1, 4, and 8 were mapped to a reference *de novo* assembly (GenBank: CP032766.1) and confirmed that the observed duplication in J767 remained stable throughout the eight serial passages (Fig. 3A). However, in lineages of J766, a new duplicated region emerged (position 2,525,000–2,640,000), first detected at passage 2 and steadily increasing in abundance through passage 8 (Fig. 3B). Duplication within the genome of J766 became detectable within two passages of subculturing, perhaps because it existed undetected within a small subpopulation and rapidly expanded during serial passage. The hypothesis that the duplication existed in low frequency before passage is corroborated by the fact that all five lineages accumulated the same duplication throughout the eight passages.

Stability of a large inversion was monitored by mapping long PacBio sequencing reads from replicate passages 1 and 8 of J818/J820 to a reference *de novo* assembly

Downloaded from https://journals.asm.org/journal/msystems on 15 October 2025 by 24.117.150.43.

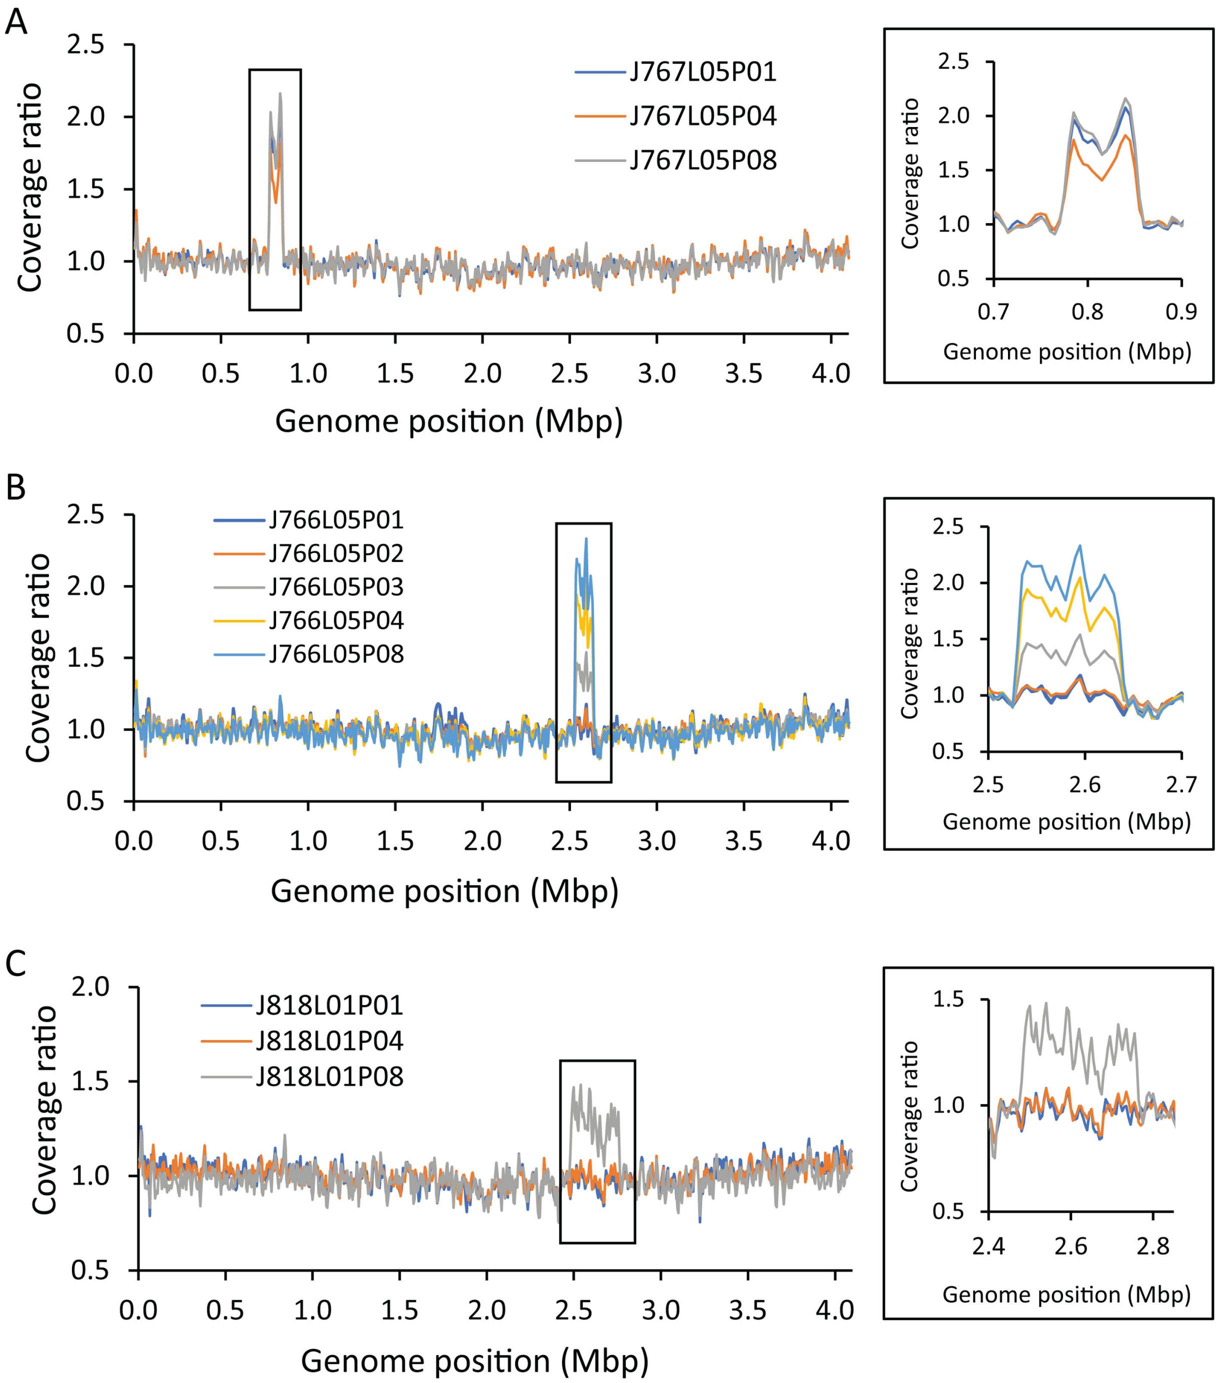

FIG 3 Dynamics of genome rearrangement during laboratory culture. The plots compare coverages for different passages (P01, P02, P03…) of isolates J767 (A), J766 (B), and J818 (C) using the same lineage per isolate. The plots show increases in depth in different regions in all three isolates. Zooming in at the increased coverage (inset, top right of each panel) confirmed the presence of a duplication stably maintained from passage 1 of J767 (A) and the progressive accumulation of a subpopulation of isolate J766 containing a duplication (B) distinct from that of J767. (C) WGS analysis of the serial passage of the pair of isolates J818/J820 initially investigated for a regional inversion revealed a regional duplication not previously observed at passage 8. Genome coordinates are in kilobases (kb) as indicated in the *x*-axis. The *y*-axis indicates the number of times each position on the genome coordinate is observed.

(GenBank: CP043236). The primary difference between the genomes of J818 and J820, an inverted segment of approximately 1 Mbp, appeared stable throughout the eight serial passages (Fig. 2D), and no evidence of inversion was observed during the serial passage in any of the replicate lineages. However, a new duplication event emerged in one of the five replicates during the final passage (Fig. 3C) for both J818 and J820. Mapping Illumina

Downloaded from https://journals.asm.org/journal/msystems on 15 October 2025 by 24.117.150.43.

short-read sequences at passages 1, 4, and 8 suggested that the duplication event likely occurred between passages 5 and 8—similar timing with changes observed in previous subculturing experiments analyzed by PFGE (31).

Frequent Prn and Fim2 deficiency among isolates

Characterizing the 705 isolates from the 149 patient sets included a protein production screening assay and multilocus sequence typing to look for variations in vaccine immunogens within each patient set (Table S1). Most isolates did not produce detectable Prn or Fim2, with deficiency observed in 132 (89%) and 139 (93%) sets, respectively. WGS analysis showed that 87% of mutations underlying Prn deficiency were IS*481* insertion within *prn* (Table S2), consistent with findings in previous studies (14). By comparison, only 7% of sets (54, 55, 70, 73, 80, 88, 98, 100, 121) lacked detectable Fim3 (Table S1). Interestingly, two sets (131, 132) contained one isolate each deficient in Fha, and only set 134 contained one isolate deficient in Pt (Table S1). Allele typing for *fim3, prn, ptxA,* and *ptxP* showed that isolates within sets consistently displayed the same sequence type, and no variations were observed (Table S1).

DISCUSSION

Previous studies have shown that circulating *B. pertussis* diverged from vaccine reference strains through a combination of genome sequence and gene order changes (1, 25). For an in-depth analysis of these dynamics during infection, this study utilized traditional molecular assays and WGS to assess *B. pertussis* genetic variation within infected patients and during subsequent laboratory passage, respectively. The analyses described herein revealed that although bacterial populations within patients may exhibit minor genetic variation, these rarely result in detectable differences in aP vaccine immunogen production. However, the genome sequence and structural dynamics within patient diagnostic specimens highlight critical implications for accurate interpretation of molecular epidemiology and surveillance using cultured isolates.

While *B. pertussis* has historically been regarded as a monomorphic organism (18), a growing number of reports from comparative genomic analyses have indicated notable heterogeneity among clinical isolates (24, 25). Detecting genomic variation by molecular typing and WGS among replicate isolates from a single patient collected at a single time point here now adds another layer of complexity to our understanding of *B. pertussis* evolution. Specifically, such observation suggests that genomic rearrangements likely occur during bacterial proliferation within infected patients and are not artifacts of subsequent clinical laboratory manipulation. These structural changes, both inversions and duplications, underscore the remarkable genomic plasticity of *B. pertussis,* primarily driven by high-copy numbers of IS*481* (23).

Previous studies of repeated subculture with *B. pertussis* have yielded mixed findings. One study reported that sporadic *B. pertussis* PFGE profile changes can occur during serial passaging (31), and another observed mutation leading to reduced expression of type III secretion (32–34), while another reported no genomic alterations after 11 consecutive passages (25). The passage results here suggest that large genomic inversions, but not duplications, remain stable during repeated subculture, suggesting that perhaps previously reported changes in PFGE profile reflected duplications only. While duplications appeared frequently during passage in this study, the question remains whether this rearrangement was present at low frequency within the initial population, becoming observable only through repeated culturing. However, even if true, the hypothesized increasing frequency observed in subsequent passages suggests the duplications were selectively advantageous during laboratory culture, allowing those harboring it to outcompete population members without it. The phylogenetic distribution of duplications detected in publicly available *B. pertussis* genomic data reported previously highlighted multiple homoplasies, also consistent with potential adaptation to laboratory culture (24). Perhaps direct sampling from patients at multiple time points

Downloaded from https://journals.asm.org/journal/msystems on 15 October 2025 by 24.117.150.43.

throughout infection may be essential to unraveling lingering questions regarding the delicate interplay between genomic stability and adaptability of *B. pertussis*.

Applications of high-throughput WGS in public health have transformed molecular epidemiology and surveillance of microbial pathogens with added resolution (35). However, the implementation of WGS for tracking pertussis clusters has been challenged, in part, by the pathogen's very low mutation rate, leading some to suggest that distance thresholds as low as two SNPs may define linked cases (28, 36, 37). Observed SNP differences among replicate isolates here could have implications for genomic epidemiology as case clustering results may differ depending on which isolate is selected for analysis. Similarly, although the use of PFGE for molecular characterization has declined, many previous studies noted that this assay often indicated higher levels of diversity compared to other methods, such as allele typing (19, 31). The results here suggest that PFGE may have overestimated phylogenetic diversity within pertussis epidemics due to the dynamic nature of duplications in particular and, to a lesser extent, inversions. Perhaps culture-independent WGS (38) directly from nasopharyngeal specimens, as well as controlled human infection model experiments, can shed more light on *B. pertussis* genomic diversity within single infections to both detect and account for such variation.

It is important to acknowledge the limitations of this study. While the data presented here provide valuable insights, there were few isolates per patient, limiting the detection of genetic variations that may have been present at a low frequency. Additionally, to minimize the burden on participating surveillance sites, this study focused on replicate isolates collected at a single time point (e.g., clinical diagnosis). In contrast, longitudinal studies could provide deeper insights into genetic diversification throughout the course of infection. Critically, both limitations suggest that the present study could not capture the full extent of variation present within the bacterial population infecting individual patients, and the number of genomic rearrangements observed here is likely underestimated. Similarly, the very low SNP distances observed within sets here prohibit confidently determining whether such mutations emerged during infection or represent colonization from diverse sources within a transmission network. Numerous studies have established that bacterial populations accumulate genetic diversity during transmission and even within single colonies on agar media, thus potentially colonizing patients with heterogeneous genotypes (39–41). However, the present study underscores pertussis-specific challenges presented by the pathogen's relatively low mutation rate, limiting genomic epidemiology and surveillance.

In conclusion, integrating genomic, molecular, and laboratory passage data in this study increased our understanding of *B. pertussis* genome plasticity. These findings underscore the importance of ongoing surveillance and highlight the potential challenges posed by genetic diversity in the context of pertussis control. As *B. pertussis* evolves, adaptive public health programs will be essential to effectively combat this persistent respiratory pathogen. It is important that future research continues to monitor genetic diversity, including genome rearrangements, to better understand mechanisms driving *B. pertussis* evolution that may affect pertussis control.

MATERIALS AND METHODS

Isolate collection

All *B. pertussis* isolates used in this study were collected between 2016 and 2022 through enhanced pertussis surveillance (EPS) (7) at five participating sites, each providing isolates from a convenience sample of patients that were not representative of all captured cases in each region: Colorado ($n = 42$), Connecticut ($n = 4$), Minnesota ($n = 67$), New York ($n = 9$), and Oregon ($n = 29$). All patients met the Council of State and Territorial Epidemiologists (CSTE) pertussis case definition except for two patients from Oregon. Nasopharyngeal specimens positive for pertussis were confirmed by culture. Multiple colonies were recovered from each patient specimen, harvesting colonies with maximal

Downloaded from https://journals.asm.org/journal/msystems on 15 October 2025 by 24.117.150.43.

morphological differences where possible and submitted as a “set” of 2 to 10 replicate isolates (average = 5) to CDC for characterization. Colony morphological differences were not systematically tracked during subsequent culturing at CDC. In total, 705 isolates from 149 patients were included (Table S1). The two patients from Oregon, having sets 73 and 98 (Table S2), were inadvertently characterized in these studies as EPS sets and counted among the 149 patients; only these two patients did not meet the CSTE pertussis case definition or fall within the EPS catchment area but suited the laboratory characterization parameters. Patient demographics can be found in Table S3.

Bacterial cell culture and DNA extraction

Isolates were cultured on Regan-Lowe charcoal agar media without cephalexin for 72 hours at 37°C and harvested as previously described (28) for DNA extraction. Genomic DNA extraction was performed using the Maxwell RSC Instrument and the Maxwell RSC Whole Blood DNA Kit (Promega, AS1520). All DNA samples were quantified and qualified using a NanoDrop 8000 Spectrophotometer (Thermo Fisher Scientific Inc., Wilmington, DE) and a Qubit Fluorometer 3.0 with the Qubit dsDNA Broad Range Assay Kit (Life Technologies, Waltham, MA).

Pulsed-field gel electrophoresis

PFGE was performed on all 705 isolates at CDC, as previously described (42). Briefly, extracted DNA was embedded in agarose plugs and digested with the restriction enzyme XbaI. Agarose gels (1%) were prepared, and the restricted DNA plugs were placed onto the gel, and electrophoresis was conducted in 0.5× Tris-borate-EDTA buffer at 6 V/cm for 18 hours at 14°C with a ramped switch time of 2.2 to 35 s. Gels were stained with GelRed, and bands were visualized using UV light. Captured digital TIFF images were analyzed using BioNumerics software, version 5.01 (Applied Maths, Inc., Austin, TX), and profiles were compared to the CDC database and assigned based on bands in the range of 125 to 525 kb.

Whole-genome sequencing and assembly

Whole-genome shotgun sequencing of isolates was performed using a combination of the PacBio Sequel II (Pacific Biosciences, Menlo Park, CA) and Illumina MiSeq (Illumina, San Diego, CA) platforms as described previously (26). Briefly, Illumina paired-end libraries were prepared with the NEBNext Ultra II DNA Library Prep Kit (New England Biolabs, Ipswich, MA) and sequenced on a MiSeq using v.2 Kit (Illumina, San Diego, CA). The Illumina raw reads were checked for quality using FastQC v.0.11.5 (43), and then trimmed and filtered with Cutadapt v.2.3 (44). Libraries were prepared for PacBio sequencing using SMRTbell template prep kit 2.0, SMRTbell Enzyme Clean Up Kit 2.0, Sequel Bind Kit 2.2, and Sequel II Sequencing Kit 2.0. A library size selection was performed using BluePippin with 0.75% agarose gels. *De novo* assembly was performed using FLYE (v.2.4.2) with default settings (45). The resulting consensus sequences were manually checked for circularity using Gepard (v.1.30) (46) and then reordered to match the start of Tohama I (GenBank accession no. NC_002929). Assemblies were further polished by mapping Illumina reads using the CLC Genomics Workbench (v.23; CLC bio, Boston, MA). Assemblies were annotated using the NCBI Prokaryotic Genome Annotation Pipeline.

Sequence variation within sets

SNPs were determined by mapping trimmed Illumina short reads to a closed genome assembly from an isolate of the same set using Snippy v.4.3.8 (47) with default settings. Pairwise SNP distances within each set were calculated from a core genome alignment using SNP-Dist v.4.0 (48) and summarized using the maximum pairwise distance. Large duplications were identified by mapping trimmed Illumina short reads to a closed genome assembly from an isolate of the set using bowtie v.2.2.9 (49) and inspecting

Downloaded from https://journals.asm.org/journal/msystems on 15 October 2025 by 24.117.150.43.

the coverage depth calculated with samtools v.1.8 (50) plotted across a sliding 10 kbp window. Inversions and other rearrangements were determined by pairwise alignment of assembled PacBio genomes using MUMmer v.4 (51).

Protein production screening

Isolates were cultured on Regan-Lowe agar without cephalexin for 72 hours at 37°C. Bacterial cells were collected and suspended in 0.01 M phosphate-buffered saline (PBS) to a turbidity of 1.0, then measured using a Dade Behring MicroScan Turbidity Meter (Siemens Global, Munich, Germany). Cells were pelleted by centrifugation at 10,000 × *g* and resuspended in Xtractor lysis buffer (Clontech, CA, USA) containing 25 U of Benzonase (Sigma-Aldrich, MO, USA) at a 1:1 ratio (vol/vol). The mixture was vortexed gently for 10 min at room temperature and centrifuged, and lysis buffer supernatant was discarded. Cell lysate pellets were resuspended in PBS for analysis, as previously described (52, 53).

The electrochemiluminescent antibody capture assay was performed using the Sector S6000 platform (Meso-Scale Discovery, Maryland, USA). Purified Prn, Fha, Pt, Fim2, and Fim3 at 1 µg/mL (GlaxoSmithKline, UK) were used as positive controls for the respective immunogens. Respective 96-well plates per immunogen (Meso-Scale Discovery) were coated with 30 µL of 1/1,500 working dilution (wd) of rabbit anti-Prn polyclonal antibody (Alpha Diagnostics, TX), capture sheep Fha anti-serum at 1/33,000 wd, capture sheep Pt anti-serum at 1/10,000 wd, capture human anti-*B. pertussis* serum at 1/1,500 wd, and capture sheep Fim3 anti-serum at 1/20,000 wd (NIBSC, UK), sealed, and incubated overnight at 4°C. The next day, plates were washed three times with at least 200 µL of wash buffer containing PBS and 0.05% Tween (Fisher Scientific, PA, USA). Blocking buffer (150 µL) containing Blocker A (1.0 g, Meso-Scale Discovery), milk powder (2.5 g, Fisher Scientific, PA, USA), goat serum (1.0 mL, Sigma-Aldrich, MO, USA), and PBS (46 mL) were added to the plates, sealed, and incubated on a plate shaker at room temperature (RT) for at least 30 min. Blocking buffer was replaced with 25 µL/well of cell lysates and incubated at RT for 1 hour. Plates were washed 6× with at least 200 µL of wash buffer and incubated for 45 min at RT or 4°C overnight with 25 µL of sheep anti-Prn detection antibody at 1/4,000 wd, mouse anti-Fha 1/5000 wd, mouse anti-Pt subunit 1 at 1/1,000 wd, mouse anti-Fim2 at 1/1,500 wd, and mouse anti-Fim3 at 1/20,000 wd, respectively (NIBSC, UK). Plates were washed three times with at least 200 µL of wash buffer and incubated for 45 min at RT or 4°C overnight with 25 µL/well of donkey anti-sheep Sulfo-tag secondary antibody at 1 µg/mL for Prn and goat anti-mouse Sulfo-tag at 1 µg/mL for Fha, Pt, Fim2, and Fim3 (Meso_Scale Discovery). Plates were washed three times with at least 200 µL of wash buffer, then replaced with 150 µL 2× read buffer. Luminescence was measured with a Sector Reader (Meso-Scale Discovery). A twofold dilution series with 2 µg/mL purified Prn, Fha, Pt, Fim2, or Fim3 was performed and fit with a four-parameter logistic regression using the instrument software to confirm the absence of nonspecific cross-reactivity. Isolates were qualitatively defined as either Prn-, Fha-, Pt-, Fim2-, or Fim3-producing or -deficient based on their signal intensity compared to positive and negative controls measured on the same plate to account for variability between plates (52). The assay was repeated for confirmation for any isolate producing <50% signal intensity compared to the control.

Serial laboratory passage

Two pairs of isolates (J766/J767 and J818/J820) were selected for serial laboratory passaging at CDC to assess the stability of genomic rearrangements. Bacterial cell culture was performed as described above, and five replicate lineages of each isolate were transferred to fresh Regan-Lowe charcoal agar plates without cephalexin (RL) every 72 hours. Each lineage was started by rubbing a single bead from a frozen stock on RL. After 72 hours, plates were checked for contamination, then half of the growth was harvested using a cotton swab and resuspended in 600 µL of saline for DNA extraction, library prep, and sequencing as described above. One-third of the plate growth was used to prepare

Downloaded from https://journals.asm.org/journal/msystems on 15 October 2025 by 24.117.150.43.

cryobeads (Microbank, Pro-Lab Diagnostics, Round Rock, TX) for long-term storage at −70°C, according to the manufacturer's instructions. The remaining growth was used to inoculate a fresh RL plate. This process was repeated eight times. Unique identifiers were assigned to track each isolate's replicate lineages (L) and passages (P). For example, "J766L01P01" indicates J766 lineage 1 and passage 1.

The emergence of SNPs and large duplications during passages was investigated by mapping Illumina reads to genomes assembled before passage in a similar manner as described above. Potential genome rearrangements occurring during the passage of J818 and J820 were investigated by mapping PacBio reads to their previous genome assemblies using Minimap2 (54, 55) and calling structural variants with Sniffles (56).

ACKNOWLEDGMENTS

We thank the Enhanced Pertussis Surveillance Network, Amy Rubis (CDC), Mili Sheth (CDC), the CDC Genome Sequencing Laboratory, the CDC Laboratory Leadership Service Program, and the United States Public Health Service (USPHS) Commissioned Corps for their support.

This work was made possible through support from CDC's Advanced Molecular Detection (AMD) program.

REVIEW **Open Access**

Genomics and proteomics in liver fibrosis and cirrhosis

Rebekka A Hannivoort[1,2], Virginia Hernandez-Gea[1] and Scott L Friedman[1*]

Abstract

Genomics and proteomics have become increasingly important in biomedical science in the past decade, as they provide an opportunity for hypothesis-free experiments that can yield major insights not previously foreseen when scientific and clinical questions are based only on hypothesis-driven approaches. Use of these tools, therefore, opens new avenues for uncovering physiological and pathological pathways. Liver fibrosis is a complex disease provoked by a range of chronic injuries to the liver, among which are viral hepatitis, (non-) alcoholic steatohepatitis and autoimmune disorders. Some chronic liver patients will never develop fibrosis or cirrhosis, whereas others rapidly progress towards cirrhosis in a few years. This variety can be caused by disease-related factors (for example, viral genotype) or host-factors (genetic/epigenetic). It is vital to establish accurate tools to identify those patients at highest risk for disease severity or progression in order to determine who are in need of immediate therapies. Moreover, there is an urgent imperative to identify non-invasive markers that can accurately distinguish mild and intermediate stages of fibrosis. Ideally, biomarkers can be used to predict disease progression and treatment response, but these studies will take many years due to the requirement for lengthy follow-up periods to assess outcomes. Current genomic and proteomic research provides many candidate biomarkers, but independent validation of these biomarkers is lacking, and reproducibility is still a key concern. Thus, great opportunities and challenges lie ahead in the field of genomics and proteomics, which, if successful, could transform the diagnosis and treatment of chronic fibrosing liver diseases.

Keywords: cirrhosis, genomics, liver fibrosis, mass spectrometry, microarray, proteomics

Introduction

Liver fibrosis results from a wound-healing response to chronic injury, which leads to excessive matrix, or scar deposition. This scar tissue can restrict blood flow due to contraction of the organ, leading to progressive liver damage and cirrhosis (the end stage of fibrosis), complicated by liver failure, portal hypertension and/or hepatocellular carcinoma [1]. Fibrosis is prominent in chronic liver diseases, including viral hepatitis, alcoholic and non-alcoholic steatohepatitis, toxic liver injury, autoimmune diseases and several genetic diseases. There have been two major priorities for therapy to reduce fibrosis: 1) to establish treatments for the diseases that lead to liver fibrosis; and, 2) to identify agents that directly slow or reverse fibrogenesis independent of the underlying disease.

A key discovery in understanding fibrosis has been the role of hepatic stellate cells (HSCs), vitamin A storing cells in the space of Disse, which, when activated, transform into myofibroblast-like cells, shedding their vitamin A content, and producing fibrogenic proteins, including collagens and tissue inhibitor of metalloproteinases-1 (TIMP-1) [2]. This review will focus on the contribution of high-throughput genomic and proteomic approaches to the study of fibrogenesis and fibrosis progression, concentrating on the most prevalent human chronic liver diseases and findings from animal models in liver tissue, isolated liver cells, cell lines and serum.

The role of genomics and proteomics in degenerative diseases and liver fibrosis

Genetic diseases can be classified as chromosomal abnormalities (for example, trisomy 21), Mendelian

disorders (single gene alterations with typical inheritance patterns, like autosomal dominant/recessive or X-linked), and complex diseases that are influenced by many genetic and environmental components. Degenerative diseases like liver fibrosis are complex illnesses [3]. The genetic contributions to these disorders are not attributable to a single gene alteration, but rather to a host of genetic susceptibilities defined by single nucleotide polymorphisms (SNPs) that predispose an individual to a disease. The susceptibility to an accumulation of environmental influences is either enhanced or reduced by genetic factors, thereby defining an individual's disease risk. Studies investigating these genetic traits are complicated, because there are many genes that influence the risk for complex diseases, yet the impact of each single genetic variant by itself is small. Therefore, large numbers of subjects are needed to provide sufficient statistical power to yield robust conclusions. Currently, there are almost 13 million SNPs catalogued in the NCBI human SNP database. Approaches to identify SNPs that are linked with a specific disease range from efforts to sequence specific disease-causing genes to genome scans requiring sequencing of large numbers of known SNPs that may or may not be associated with the disease.

Genomic and proteomic screening methods are often used to identify classes of genes that are differentially expressed in disease. These classes provide the investigator with potential pathways that could be involved in the regulation of this disease, thereby narrowing the focus of subsequent studies to uncover disease mechanisms and potential targets for therapy. By not limiting the study to pathways already associated with a disease, many new pathways not previously implicated are now under investigation [4].

This prospect is especially compelling in degenerative diseases like liver fibrosis, as these conditions often develop slowly, and therapies may not be necessary for all subclasses of patients [5]. Regardless of the etiology of liver fibrosis, some people progress rapidly towards cirrhosis, whereas others never develop fibrosis in the first place, or have slow progression of their fibrosis. It seems very unlikely that this phenomenon can be attributed solely to environmental influences. Identifying which patients are unlikely to ever progress to cirrhosis may prevent overtreatment of many patients.

Another use for these screening methods is to identify expression profiles, or patterns of expression of many genes, that in aggregate correspond with disease outcome or the response to therapy. By analyzing these different gene/proteome classes, investigators may ultimately predict an individual patient's response to therapy more accurately, or identify those who are at greatest risk of progression, thereby refining treatment decisions.

The need for non-invasive markers in the assessment of fibrosis progression

The need to assess hepatic fibrosis progression is becoming more important as the incidence of advanced liver disease continues to rise, especially due to viral hepatitis and fatty liver disease. Liver biopsies are currently the 'gold standard' for determining the presence and progression of liver fibrosis. They are performed percutaneously, via transjugular access, or during abdominal surgery. Liver biopsies have a low complication rate; however, significant hemorrhage may rarely occur, requiring hospitalization in approximately 2% of the patients; moreover, some patients have contraindications for liver biopsy [6-8]. Additionally, analysis of liver biopsy is often undermined by sampling error and inter-observer variation [[6,9-15]. Studying mRNA and protein disease profiles in liver biopsies is challenging, as tissue sample sizes are small, especially for protein analysis, and the biopsies contain a mix of many different cell types, including hepatocytes, hepatic stellate cells, Kupffer cells, endothelial cells, lymphocytes, red blood cells and bile duct epithelial cells. To study a single cell population from tissue sections requires laser-capture micro-dissection, which yields even less mRNA and protein than biopsy [15].

Close follow-up of liver disease by serial biopsy is not practical due to its invasive nature, fueling the need to find alternatives for liver biopsy. A less invasive and more accurate diagnostic tool would aid in diagnosis of fibrosis, follow-up of established therapies and evaluation of experimental therapies. Moreover, hepatocellular carcinoma (HCC) is one of the main complications of cirrhosis, and early detection markers that distinguish HCC from cirrhosis could significantly reduce morbidity and mortality. In the past ten years, genomic, transcriptomic and proteomic studies have provided candidate biomarkers for fibrosis assessment. Thus, in combination with standard laboratory serum analysis, these have led to novel fibrosis assessment tools using indirect and direct fibrosis markers, like FibroSpect (Prometheus Laboratories; San Diego, CA, US), FibroTest (BioPredictive;Paris, FR) and Fibroscan (Echosens; Paris, FR), ActiTest (BioPredictive;Paris, FR) and APRI (public domain) [16-20]. For a more exhaustive overview of currently used serum biomarkers, see a recent review by Smith *et al.* [21].

These fibrosis assessment tests have shown promising results, but a number of pitfalls are encountered, including limited availability, inter-laboratory variation, cost, insufficient resolution to differentiate between intermediate stages of fibrosis and false positive results due to other conditions, such as increased venous pressure or steatosis [22-29].

Because current methods for non-invasive assessment of liver fibrosis lack resolution, particularly in the intermediate fibrosis stages, more research is being directed towards genomics and proteomics in the search of biomarkers that provide a close association with fibrosis stage [30-35].

Technical aspects of genomics and proteomics in chronic liver disease

Genomics and transcriptomics

Genomics comprises the study of the genetic information (DNA, or RNA in certain viruses) of an organism. Transcriptomics aims to elucidate the transcripts of the genome or gene expression levels on the RNA level under varying conditions as changes in mRNA expression do not necessarily correspond with changes in protein expression, since alternative splicing, protein production, degradation and post-translational modifications influence protein stability and function [36,37].

The cDNA microarray is the most frequently used high-throughput screening method for gene expression profiling. These 'lab-on-a-chip' assays contain specified DNA oligonucleotide probes in spots on a chip that hybridize with oligonucleotides from tissue or cells providing a quantitative assessment of the transcribed genes [42-44]. Thousands of genes can be analyzed simultaneously with cDNA microarray and variants on this technique include specialized arrays that can detect SNPs and alternative splice variants (exon junction arrays) [38-41].

Serial analysis of gene expression (SAGE) analyzes the transcriptome by cloning strings of short cDNA fragments into bacteria, sequencing the cDNA fragments and then counting the number of cDNA fragments. This technique can yield information on both gene expression and alternative splicing and can help identify previously unknown genes [42,43].

Target genes that are revealed by the genomics/transcriptomics screens are generally validated by reverse transcription quantitative polymerase chain reaction (RT-qPCR), which is more quantitative and more reproducible than microarray, requires less mRNA and is more sensitive for genes that are expressed at low levels.

Proteomics

Proteomics is the study of the proteome in a cell compartment, tissue or organism comprising all proteins that are encoded for in the genome. Mass spectrometry (MS) is the key technique in proteomics. Many variants of mass spectrometers are currently in use, but they all rely on the same concept: to determine the accurate mass of a protein by measuring the mass-to-charge (m/z) ratio. In short, mass spectrometers consist of an ion source, a mass analyzer and a mass detector. After ionization, proteins and peptides travel through the mass analyzer, which evaluates their ratio of charge (z) versus mass (m). The mass detector counts the number of molecules per charge-to-mass ratio, and can provide the user with an output as a mass spectrum, with the m/z ratio on the x-axis and the molecule count per m/z on the y-axis [44].

MS is preceded by a separation step of proteins, either through 2D-polyacrylamide gel electrophoresis (2-DE/2D-PAGE), liquid chromatography (LC) or gel electrophoresis (DIGE) [45-47]. Once the protein spots are excised from the gel and digested, they can be processed through one mass analyzer (MS) to identify peptide mass, or two mass analyzers (MS/MS) to determine amino acid sequence.

MS requires ionization of proteins and peptides and two soft-ionizing techniques have been developed: matrix-assisted laser desorption/ionization (MALDI) and Electrospray ionization (ESI). Both techniques charge molecules that are subsequently analyzed by one or two mass analyzers (MS or versus tandem MS/MS). Time-of-flight (TOF) mass analyzers deduct peptide mass by measuring the time it takes for a charged peptide to travel through a vacuum tube in an electric field and can also be combined with one (Q-TOF) or two quadrupoles (Q-Q-TOF), which uses an oscillating electric field to selectively allow for molecules with a specific range of m/z ratios to proceed without collision [48].

When extremely high resolution is required, Fourier transform-ion cyclotron resonance (FT-ICR) MS or orbitrap can be used. The charged molecules are injected into a Penning ion trap where detectors measure the signal of molecules that pass. The m/z ratio determines the frequency with which the ion passes over the detector [49-51].

Surface-enhanced laser desorption/ionization (SELDI) analyzes protein mixtures that selectively bind to a biochip with the characteristics of choice. It needs only a small amount of crude sample (for example, serum or small liver biopsies), and is suitable for profiling multiple low-molecular-weight proteins. SELDI does not provide direct identification of the proteins. However, the peak profiles generated by SELDI can be useful by themselves in diagnostics, or in predicting prognosis and/or treatment response. Since manual labor is minimal, SELDI is by itself a suitable technique for high-throughput screening, especially for serum biomarkers; however, the cost is still too high for application on a large clinical scale [52-54]. For an excellent overview of the different types of mass spectrometers and their individual strengths and weaknesses, see a review by Domon and Aebersold [55].

A different type of high-throughput screening of proteins is the protein microarray. It functions much like a cDNA microarray, but probes are constructed out of proteins, antibodies or DNA constructs containing protein binding sequences that can capture proteins on a chip [56].

Technical pitfalls

Technical variations are largely responsible for the low reproducibility between studies by different research groups. Differences in patient characteristics can significantly alter genomic and proteomic profiles. Proteome studies are especially difficult because proteins cannot be amplified, unlike DNA and mRNA. Therefore, scientists have to rely on fractionation, enrichment/depletion and solubilization protocols prior to MS to prevent overload with the most abundant proteins present in the serum urine

Overview of genomics and proteomics in chronic liver disease

Most chronic liver diseases lead to fibrosis and cirrhosis in a significant subset of patients. While many common pathways drive fibrogenesis in all these diseases, there are also disease-specific pathways that contribute to fibrosis. An increasing number of studies are comparing the transcriptome and proteome of patients with different types of chronic liver injury to unearth disease-specific abnormalities in gene or protein expression.

In the following section we focus on disease-specific genomic and proteomic studies in both animal models and human diseases.

In vivo *and* in vitro *animal models of fibrosis*

Not all human liver diseases can be reproduced accurately in animal models, and thus surrogate models are being developed to study mechanisms of chronic liver injury and fibrosis.

Rodent studies reviewed below have analyzed a variety of fibrosis progression and resolution models, and have evaluated liver tissue, cell isolates, serum and urine proteomes. Considerable additional effort will be required to systematically compare proteomes between different disease models, and to accomplish the translational step of comparing these proteomic changes to human liver diseases.

Liver tissue proteome analysis

A number of liver tissue proteome analyses have been reported in rodent models. Low *et al.* characterized the proteome of rat livers treated with thioacetamide (TAA). Using several time points, they proposed that TAA causes chronic liver injury leading to liver fibrosis through down-regulation of enzymes related to fatty acid β-oxidation, branched chain amino acids and methionine breakdown through depletion of succinyl-CoA and subsequent alterations in heme and iron metabolism [57]. Using carbon tetrachloride (CCl_4) as a model for toxic liver injury in mice, and Abcb4-knockout mice as a model for sclerosing cholangitis to study differentially expressed proteins in liver tissue, Henkel *et al.* combined DIGE with MALDI-TOF MS and peptide mass fingerprint database search. They identified 20 differentially expressed genes in the CCl_4 model and 8 genes in the Abcb4-knockout model compared to control mice [58]. A number of studies have characterized proteome changes after ethanol feeding in rats. Shepard *et al.* observed that many mitochondrial proteins are acetylated in livers of rats that are chronically ethanol-fed [59]. A study in ethanol-fed rats treated with S-adenosylmethionine (SAM) demonstrated that the proteins affected by ethanol and SAM treatments were chaperones, beta oxidation proteins, sulfur metabolism proteins and dehydrogenase enzymes involved in methionine, glycine and choline metabolism [60]. Kharbanda *et al.* treated ethanol-fed rats with betaine, which restores the metabolic ratio of liver S-adenosylmethionine to S-adenosylhomocysteine. Ethanol significantly reduced carbonic anhydrase-III protein levels, which can lead to decreased resistance against oxidative stress [61].

Rodent studies are also being used as models for fibrosis resolution after the chronic injury is removed. Liu *et al.* characterized liver tissue proteome changes during spontaneous recovery after TAA-induced micronodular cirrhosis in rats. Using 2-DE and MALDI-TOF, they identified the up-regulation of GST-P2 that peaked after two weeks of recovery [62].

Employing a cDNA microarray gene chip and 2D-DIGE with MALDI-TOF/MS-MS, Kirpich *et al.* found that glutathione S-transferases mu-1, pi-1 and selenium-binding protein 2 are decreased at both gene and protein levels in a mouse model of NAFLD [63].

Enoyl-coenzyme A hidratase, an enzyme that catalyzes the second step of mitochondrial fatty acid beta-oxidation, has been described by Zhang *et al.* to be down-regulated in rats with HFD-induced hepatic steatosis [64].

Hepatic stellate cell proteome analysis

Activation of HSCs is a key event in fibrogenesis and can be reproduced *in vitro* by prolonged culture on plastic or collagen. The changes in protein expression during activation can provide novel targets for antifibrotic therapy. However, differences between *in vitro* and *in vivo* HSC activation need to be taken into account. Kristensen *et al.* isolated hepatic stellate cells from rats and compared the proteome of quiescent cells with that of either culture-activated cells or *in vivo* activated cells from rats treated with CCl_4 for eight weeks. Following 2-DE, proteins were digested by trypsin, and ESI-MS/MS was used to sequence the proteins that were differentially expressed. They detected 16 proteins showing differences based on the model of activation [65].

A study by Kawada *et al.* explored the proteome of *in vivo* (thioacetamide) and *in vitro* activated rat HSCs, describing a protein that was induced with HSC activation: stellate-cell activation-associated protein (STAP), which may act as an anti-fibrotic scavenger of peroxides during liver injury [66].

Deng *et al.* employed human hepatic stellate cells (LX2) treated and untreated with taurine and performed a combination of two-dimensional gel electrophoresis and ultra-performance liquid chromatography-electrospray ionization-tandem mass spectrometry (UPLC-ESI-MS/MS). They postulate a beneficial role of taurine in hepatic fibrosis, as they were able to detect an increased rate of stellate cell apoptosis after treatment [67].

Serum and urinary proteome analysis

Animal models could provide general serum markers that correlate with fibrosis stage and have the advantage of easier access to liver tissue at set time points for histological comparison. In thioacetamide (TAA) and bile-duct ligation treated rats, Xu *et al.* indentified and sequenced a 3.5 kDa histidine-rich glycoprotein, which had > 92% specificity and > 97% sensitivity for identifying liver cirrhosis. Previous studies have shown a beneficial effect of bone marrow cell (BMC) transplantation in CCl_4-induced cirrhosis in mice, improving liver regeneration, function and fibrosis. Yokoyama *et al.* found six differentially expressed proteins in the serum by 2-DE, 48 hours after BMC transplantation, compared to non-transplanted mice. They suggested ApoA1 protein levels as a proteomic analysis of serum marker proteins in recipient mice with liver cirrhosis after bone marrow cell transplantation. marker for liver regeneration after BMC transplantation [68]. Serum taurocholic acid has also been recently proposed as a marker of early hepatic damage based on the Shimada *et al.* study. The identified elevated serum taurocholic acid concentration by SPE-MALDI-TOF MS in mice CCl_4 induced liver injury [69].

A recent publication looked at urinary samples to find biomarkers for CCl_4-induced liver fibrosis providing a potential alternative to serum samples for non-invasive diagnostics and follow-up in liver fibrosis (70).

Chronic hepatitis C viral infection (HCV)

In patients with HCV, early knowledge of which patients have rapidly progressing fibrosis could be very beneficial in the decision-making process of whether to treat patients aggressively with antiviral therapy. A recent review by Walters and Katze explored the relationship among the gene expression profile of HCV patients, viral clearance and treatment response, shedding light on potential virus-host interactions, which may emerge as future therapeutic targets [71].

Staging of fibrosis

The liver proteome of HCV-patients can provide HCV-specific and general fibrotic pathways that could lead to novel therapeutic targets, or predict the natural disease progression or therapeutic response in the individual patient. Recent findings point towards alterations in fatty acid oxidation, oxidative phosphorylation and structural proteins in advanced fibrosis. An overview of high-throughput studies analyzing pathways and proteins involved in fibrosis due to HCV is represented in Table 1.

Diamond *et al.* have described a pattern of 210 proteins that correlate with fibrosis stage in 1,641 HCV-infected patients. They were able to cluster the patients in fibrosis stages 3 to 4 versus stages 1 to 2 using these protein expression profiles. Functional analysis indicated reduced expression of genes involved in fatty acid oxidation and oxidative phosphorylation in advanced fibrosis [72]. Several cell structure-associated proteins were uncovered in the cirrhotic septa of seven HCV patients (METAVIR stage F4) when Mölleken *et al.* compared the proteomic profiles of microdissected cirrhotic septa versus parenchymal liver cells using 2-DE and LC with ESI-MS/MS, in the search for new serum biomarkers for fibrosis. MFAP-4 could predict the presence of fibrosis with high accuracy in both HCV- and alcohol-induced fibrosis, but diagnostic accuracy decreased significantly for the discrimination between fibrosis stages 2 to 4 [73].

Regarding serum markers, none of these serum markers can adequately distinguish intermediate fibrosis stages, even though the progression from mild to intermediate fibrosis is an important predictor of further fibrosis progression. White *et al.* reported three up-regulated proteins (α2-macroglobulin, haptoglobin, albumin) and four down-regulated proteins (complement C-4, serum retinol binding protein, apolipoprotein A1, and two isoforms of apolipoprotein A4) in the serum of HCV patients with advanced fibrosis (METAVIR stage F3/4, n = 23) versus no or mild fibrosis (METAVIR stage F0/1, n = 21) [74]. Three of these proteins are already being used in the FibroTest [75]. This study was limited by a small sample size, and the four new potential biomarkers could not be validated in a larger patient group. Gangadharan *et al.* found a decrease in several proteins, including apolipoprotein L1, prealbumin, albumin, haptoglobin and complement components, whereas other proteins, such as CD5 antigen-like (CD5L), 2-macroglobulin and immunoglobulin components, were induced in fibrosis when they studied the serum proteome of HCV patients with varying levels of fibrosis and healthy controls, using 2-DE and LC with Q-TOF MS/MS [76].

A novel set of four cDNA peripheral blood mononuclear cell markers (a2-macroglobulin, haptoglobin, mitogen-activated protein kinase kinase 3, and alanine aminopeptidase N) accurately predicted the stage of liver fibrosis in HIV/HCV co-infected patients with an area under the receiver operating curve (AUC ROC) of 0.852 [77].

L Yang *et al*. recently analyzed 24 liver samples from patients with chronic HCV by DIGE and Isobaric tags for relative and absolute quantitation (iTRAQ) and identified 2 proteins as biomarker candidates for predicting hepatic fibrosis: complement C4-A and inter-alpha-trypsin inhibitor heavy chain H4 [78,79].

Novel biomarker candidates to predict hepatic fibrosis in hepatitis c identified by serum proteomics

Fibrosis progression has also been related to galectin-3-binding protein (G3BP). Cheung *et al*. found increased levels in patients with hepatitis C-related cirrhosis when compared with mild and moderate fibrosis in 76 serum and 20 tissue human samples [80].

Prediction of fibrosis progression

Prediction of fibrosis progression is crucial for adequate patient selection in clinical trials, and, thus, Huang *et al.* studied the genome of 1,468 patients with chronic hepatitis C infection and known fibrosis stage. They developed a Cirrhosis Risk Score (CRS) consisting of SNPs in seven genes, which could predict fibrosis progression significantly better than clinical parameters. Four SNPs were in known genes: antizyme-inhibitor-1, toll-like receptor 4, transient receptor potential cation channel, subfamily M, member 5 and aquaporin 2 [81]. This initial study was independently validated two additional studies [82,83], and is especially exciting, as it is the first evidence that host genetics significantly influence fibrosis progression and, thereby, provides a means for selecting patients that will benefit most from aggressive antiviral or antifibrotic treatment.

At the proteomic level, when plasma from cirrhotic HCV patients is analyzed by SDS-PAGE and MS, both chains of the complement C3 and C4 show a significant decrease in comparison with samples from healthy patients [84,85].

Prediction of treatment response

Transcriptomic and proteomic studies point to a crucial role of interferon signaling pathways in the prediction of treatment response, where high pre-treatment interferon signaling is associated with poor virological response. Recent genomic studies have identified SNPs in several interferon-related genes, especially interleukin 28b, that are powerful predictors of virologic response indicating that genomics can be a powerful tool in the prediction of treatment response.

A recent publication by Asselah *et al.* demonstrated that liver gene expression can predict outcome of patients with chronic hepatitis C infection after treatment with pegylated interferon and ribavirin. They studied cDNA of non-responders (NR), and SVR using RT-PCR for 59 genes. Three genes were significantly induced in NRs versus SVRs: interferon alpha-inducible protein 3, interferon alpha-inducible protein 27 and interferon alpha-inducible protein 2. Supervised class prediction analysis identified a two-gene (interferon-alpha-inducible protein 27 and CXC chemokine ligand 9) signature, with a predictive accuracy of 100% in NRs and of 70% in SVRs. Although no high-throughput analysis was performed, this paper provides a basis for further exploring the use of genomic and proteomic information to predict individual treatment response, and may be useful for selecting those patients who will benefit from treatment [86].

Chen *et al*. analyzed liver tissue using cDNA microarray to identify a gene signature that can predict treatment outcome. A key finding was that interferon stimulated gene 15 (ISG15) protein induction was more pronounced in hepatocytes in non-responders, but in Kupffer cells in responders [75]. In a liver tissue microarray study by Hayashida *et al*., a different set of genes was found to predict treatment response in patients treated with interferon alone, or interferon/ribavirin co-treatment. In the interferon monotherapy patients, main predictors were genes involved in the interferon signaling pathway, lipid metabolism, complement and oxidation/reduction. In the combined treatment group, genes, including *cylophylin A*, and multidrug resistance protein-hepatic gene expression during treatment with peginterferon and ribavirin emerged, identifying molecular pathways for treatment response. 1 (P-gp) [87]. Feld *et al.* discovered that low baseline liver tissue cDNA levels of interferon-stimulated genes (ISGs) predict rapid treatment response with quick induction of ISG levels, whereas high baseline ISG levels do not increase much further and predict slow treatment response, together with up-regulation of interferon inhibitory pathways [88].

As described above, recent genome-wide association studies (GWAS) have identified SNPs in the interleukin 28b (IL28B, coding for interferon-γ-3) genomic region that are associated with viral response to the current treatment of HCV, pegylated-interferon-alpha (PEG-IFNα) and ribavirin. GWAS by Suppiah *et al.* led to the discovery of a SNP near interleukin 28b (IL28B) that is associated with sustained viral response (SVR) in genotype 1 HCV patients treated with PEG-IFNα and ribavirin, with an odds ratio (OR) for the G-allele of rs8099817 of 1.64 for heterozygous carriers and 2.39 for homozygous carriers compared to non-carriers [89]. Other SNPs that were associated with SVR included Caspase 1, a known activator of interleukin 1, and interleukin 21 receptor. A simultaneous report was published by Tanaka *et al.*, identifying SNPs in IL28B in a Japanese genotype 1 HCV-patient cohort as a predictor of virologic response to PEG-IFNα and ribavirin. Initial GWAS identified rs2980275 and rs8099917 SNPs as predictors of non-response and SVR. They continued to seek SNPs in the IL28A/B region and uncovered rs8105790, rs11881222, rs8103142, rs28416813, rs4803219, rs8099917 and rs7248668 as associated with virologic response [90]. Identification of those HCV-patients who are likely to respond to therapy could lead to a shortened duration of therapy in patients with a favorable SNP genotype. Although these studies did not examine fibrogenic end-points, they are a major breakthrough in HCV treatment response research, and are excellent examples of how GWAS can identify genes and SNPs that are related to therapeutic responses.

Non-responders generally have high expression of interferon-stimulated genes (ISGs) pre-treatment that cannot be further induced by PEG-IFNα, whereas RVR patients have strong induction of ISGs on treatment. Refractory high endogenous interferon signaling in non-responders may interfere with PEG-IFNα treatment, especially in genotype 1 and 4 patients. Whether inhibition of endogenous interferon signaling could improve therapeutic response is subject to further study [91,92].

Although further validation is needed, Devitt E *et al.* using SELDI-TOF MS analyzed serum from 25 HCV infected patients during the initial 24 h of treatment with pegylated interferon α-2b and ribavirin and identified 16 differential peaks able to distinguish responders from nonresponders [93].

Chronic hepatitis B viral infection (HBV)

Approximately 400 million patients worldwide are chronically infected with hepatitis B virus (CHB). Hepatitis B virus infection causes chronic hepatitis in about 10% of infected patients, and increases the risk of developing HCC about 100-fold versus in the uninfected population. An excellent review on the role of genomics, transcriptomics and proteomics in chronic HBV-associated liver disease, recently published by Sun *et al.*, described determinants of susceptibility to persistent HBV infection, disease progression and HCC development; their review also describes the use of these technologies to understand the pathogenic mechanism of HBV and to identify biomarkers that could aid in early detection of HCC [94].

Recent high-throughput proteomic studies have identified protein patterns that correlate with fibrosis stage in HBV patients. Zhang *et al.* described a novel approach to evaluate the protein expression profile of plasma membrane and analyzed human liver samples from HBV patients in different fibrosis stages. Using 2-DE, IPGphor isoelectronic focusing system and Bio-Rad Protein II electrophoresis to the investigators identified positive correlation between fibrosis grade and annexin A2 levels [95]. Lu *et al.* analyzed plasma of 7 healthy controls and 27 HBV patients with different stages of fibrosis by 2-DIGE and identified the up-regulation of peroxiredoxin 2 as a potential biomarker of HBV related liver fibrosis [96]. Although not liver-specific, plasma gelsolin protein has been pointed out as a potential predictor of HBV progression. C Marrocco *et al.* found by 2-DE a repressed expression of the protein in plasma of eight cirrhotic HBV patients, compared to eight chronic HBV infected patients [97]. Mohamadkhani *et al.* performed a 2DE and mass spectrometry analysis in patients with either chronic hepatitis B or HBV-related cirrhosis and healthy controls. Their data suggest that progression of HBV-related liver injury is associated with a down-regulation of apolipoprotein A1 and an increase in myeloperoxidase levels [98]. However, these results still need to be validated, and their ability to distinguish intermediate fibrosis stages is not clear.

Poon *et al.* using SELDI ProteinChip arrays and the Significance Analysis of Microarray (SAM) algorithm generated a model able to predict fibrosis (Ishak score ≥ 3) and cirrhosis (Ishak score ≥ 5) with an accuracy of > 90% [99]. Liver histology (METAVIR score) of HBV-patients was compared with three sets of serum markers by Myers *et al.*: aminotransferases (ALT, AST), Fibrotest (α_2-macroglobulin, apolipoprotein A1, haptoglobin, gamma-glutamyl-transpeptidase (GGT) and total bilirubin) and Actitest (ALT). Aminotransferases and Actitest were good predictors of activity (stage A2-F3) and Fibrotest accurately predicted stage F2-F4 fibrosis, especially in the ranges of ≤ 0.20 or > 0.80. Limiting liver biopsy to patients with intermediate Fibrotest scores could prevent biopsies in about half of the patients, without affecting accuracy [100].

Wang *et al.* performed an *in vitro* study to investigate proteome differences between stably HBV transfected HepG2.2.15 versus wild type HepG2 cells by 2-DE followed by LC-ESI-MS/MS. Furthermore; they compared HepG2.2.15 cells with and without interferon-alpha (IFN-α) treatment. Proteins that were differentially expressed in HepG2.2.15 versus HepG2 cells could be classified as being involved in, for example, cytoskeletal matrix, heat shock stress, signal transduction and protease/proteasome components. IFN-α treatment induced expression of interferon-stimulated gene 15 (ISG15) and prohibitin, among others, providing potential pathways that could lead to tumor suppression and defense against viral infection. Although these results have not been validated *in vivo*, they nevertheless establish that proteomics and cell culture can be a powerful combination to uncover differences in the proteome, and can be useful for evaluating potential treatments [101].

Alcoholic liver disease (ALD)

Several genomic and proteomic studies have been published on patients with alcoholic liver disease. However, the majority of studies focus on either diagnostics or genes/proteins that differentiate alcoholic hepatitis from alcoholic steatosis, not in predicting progression towards fibrosis and cirrhosis. Nevertheless, alcoholic steatohepatitis is clearly a precursor for developing fibrosis. For example, 586 genes were differentially expressed between alcoholic hepatitis and alcoholic steatosis, and 211 genes were differentially expressed between alcoholic hepatitis and non-disease controls when Seth *et al.* compared liver tissue RNA from eight patients with alcoholic hepatitis, nine with alcoholic steatosis, and seven non-disease controls using microarray analysis. Induced genes included pathways controlling cell adhesion, immune response, oncogenesis, signal transduction and embryogenesis. The 111 down-regulated genes included pathways for protein synthesis, cell growth and maintenance, transcription, signal transduction and transport [102].

Non-alcoholic fatty liver disease (NAFLD) and non-alcoholic steatohepatitis (NASH)

The prevalence of NAFLD and NASH is on the rise, which makes these increasingly important causes of liver fibrosis, especially in countries with a Western diet containing a high fat and/or carbohydrate content. For NAFLD and NASH there is also a lack of genomic/proteomic studies specifically examining fibrogenesis and fibrosis progression, much like in alcoholic liver disease. Most genomic/proteomic studies focus on distinguishing NASH from NAFLD, and not on progression to liver fibrosis and cirrhosis. The ability to distinguish NASH from NAFLD is very relevant, however, as NASH clearly predisposes to fibrosis. Therefore, we reviewed recent publications on this topic. However, studies directed at identifying proteins related to the speed of fibrosis progression in NASH could further select patients who could benefit from treatment, improve understanding of fibrosis pathogenesis in fatty liver, and identify targets for treatment of NASH-related fibrosis.

Staging of steatosis

NASH is distinguished from NAFLD by an inflammatory component. Therefore, not surprisingly, genes that are up-regulated in NASH versus NAFLD have strong relationships with inflammatory and immune pathways. Complementary DNA microarray analysis on nine liver tissue samples from steatotic livers and nine normal livers unearthed 110 differentially expressed genes, many related to mitochondrial respiratory and mitochondrial metabolic pathways. Genes belonging to the interleukin-1 receptor family and transforming growth factor-beta were induced in steatotic livers, pointing to a deranged inflammatory pathway, even in early development of steatosis. Thirty-four genes with significant differential expression were identified in patients with NASH, when compared with non-obese controls in a study by Younossi *et al.*, using cDNA microarray analysis on liver biopsies taken during bariatric surgery to find differential expression patterns between NASH (n = 29), NAFLD (n = 12), obese non-steatotic (n = 7), and non-obese controls (n = 6) [103]. Nineteen of these genes showed no significant expression differences in obese versus non-obese controls, suggesting a stronger association of these genes to NASH. These genes were related to lipid metabolism, extracellular matrix remodeling, liver regeneration, apoptosis and detoxification. In another study, this group used parallel liver tissue gene expression and serum proteome analysis in a group of 98 morbidly obese patients. Twenty-seven patients had developed NASH, 52 patients had steatosis with nonspecific inflammation, 12 patients had steatosis alone and 7 patients had normal histology on biopsy. Using SELDI-TOF analysis on serum samples, this group found several protein peaks associated with different stages of NAFLD/NASH. However, except for fibrinogen γ, the corresponding proteins were not identified. On the mRNA level, insulin-like growth factor binding protein 1 (IGFBP1) and fatty acid CoA ligase 4 (FACL4) were differentially expressed between NASH and steatotic patients.

A recent study of the serum proteome by Bell *et al.* led to the discovery of 55 proteins that changed significantly between simple steatosis and NASH with stage F3/F4 fibrosis (advanced bridging fibrosis/cirrhosis), and 15 proteins that changed between early NASH and NASH with stage F3/F4 fibrosis. Most of these proteins are involved in the immune response, coagulation, cellular and extracellular matrix and blood carrier proteins [104]. These proteins shed light on the pathogenesis of NAFLD/NASH and could be explored as candidates for biomarkers of advancing disease. Ulukaya *et al.* were able to use serum MALDI-TOF MS peaks to accurately predict NAFLD versus controls, but could not distinguish between simple steatosis and NASH. They included 80 patients with NAFLD, and 19 controls [105]. Histologic classification of the NAFLD patients showed definite NASH in 48 patients, borderline NASH in 22 patients and 10 patients with simple steatosis. Using reverse phase protein microarray technology, Calvert *et al.* revealed deranged insulin signaling in NAFLD patients when they investigated omental adipose tissue from 99 obese patients. Liver biopsies were classified as follows: (1) no fatty liver disease present, (2) simple steatosis, (3) steatosis with nonspecific inflammation, or (4) NASH. Categories 2 to 4 were clustered as NAFLD. Protein kinase A (PKA) and AKT/mTOR deregulation and caspase 9 activation were good predictors of NASH on liver histology compared to non-progressive forms of NAFLD [106]. For more information on genomic and proteomic analysis of NAFLD and NASH, see a recent review by Wilfred de Alwis and Day [107].

Fibrosis progression in steatotic patients

Very few publications report changes in gene expression that correlate with fibrosis stage in NAFLD/NASH patients. So far, only apolipoproteins, CD5 antigen-like (CD5L) and lumican have been identified. Gray *et al.* applied 2-DE and MALDI-TOF to analyze differences in serum proteome profile between patients with pre-cirrhotic NAFLD (n = 5), cirrhotic NAFLD (n = 5) and cirrhotic NAFLD with HCC (n = 5). Four out of five spots that identified at least one of the three groups were identified as apolipoprotein isoforms. The fifth spot, identified as CD5L, was induced in cirrhotic patients and even more in patients with HCC. ELISA analysis of CD5L in a larger patient group showed a poor AUROC score for distinguishing patients with HCC from those without HCC. However, as a cirrhosis biomarker, ROC analysis showed an accuracy of 72%. CD5L could potentially be used in combination with other biomarkers for cirrhosis [108]. Charlton *et al.* identified lumican, a 40 kDa keratin sulfate proteoglycan, as significantly increased in liver tissue from patients with mild NASH (NASH with F0/F1 fibrosis) versus simple steatosis, and in patients with progressive NASH (NASH with F2-F4 fibrosis) versus mild NASH in obese patients, when analyzed with LC-Q-TOF MS/MS. FABP-1 was increased in simple steatosis patients compared to non-steatotic patients, but was paradoxically decreased in NASH patients, which suggests an impaired detergent effect against free fatty acids in progressive NAFLD patients [109].

Autoimmune liver diseases

Primary biliary cirrhosis (PBC), as well as related autoimmune disorders, is more prevalent in certain families and thus seems to have a complex genetic component, with many factors probably adding to the risk of developing PBC. Some of these genes associated with PBC are major histocompatibility complex genes and common autoimmune genes [110]. Shackel *et al.* discovered that PBC liver tissue had increased expression of Th1 and Th2 type proteins as well as connective tissue growth factor and TGF-β3 when they analyzed their cDNA microarray from liver tissue from patients with PBC (n = 4), PSC (n = 4) and non-disease controls (n = 8). Moreover, Wnt and Notch signaling pathways were induced. PSC patient samples had increased expression of apoptosis associated molecules [111]. Serum samples from 44 PBC patients and 75 controls, analyzed using WCX magnetic beads and MALDI-TOF-MS, provided 69 potential protein biomarkers. Li *et al.* used these to construct a diagnostic model for PBC using the *m/z* peaks of protein biomarkers 3445, 4260, 8133, and 16290, which showed a sensitivity of 92.9% and a specificity of 82.4% [112].

Tahiri *et al.* noticed an induction of six known potential plasma membrane expressions: liver arginase, cytokeratins 8/18, heatshock proteins (HSP) 60/70/90, and valocin-containing protein (VCP) in autoimmune hepatitis when they investigated serum samples from 65 autoimmune hepatitis type 1 patients and 90 controls consisting of healthy blood donors (n = 40) and patients with systemic diseases (n = 20) or other liver diseases (n = 30). They proposed that these proteins could be targets for auto-antibodies in autoimmune hepatitis [113]. Using protein microarray, Song *et al.* analyzed serum samples from patients with autoimmune hepatitis (n = 44), PBC (n = 50), HCV (n = 41), HBV (n = 43), systemic lupus erythematosus (SLE) (n = 11), primary Sjögren syndrome (n = 11), rheumatoid arthritis (n = 2) and 50 healthy controls. Initially they found 11 differentially expressed genes between autoimmune hepatitis and other samples. They then produced an autoimmune hepatitis-specific protein chip, and found three new antigens, ribosomal protein S20 (RPS20), Alba-like, and dUTPase, that could be used as highly specific biomarkers for autoimmune hepatitis, and validated this with ELISA [114]. Bowlus *et al.* have recently analyzed by *in situ* MALDIMS (matrix-assisted laser desorption/ionization mass spectrometry) in PBC (n = 29), PSC (n = 11), AIH (n = 7) and healthy controls (n = 10) and found a promising pattern of protein expression in bile ducts, inflammatory infiltrates and hepatocytes that may represent a feasible way to identify novel targets in these diseases [115]. Song *et al.* created a protein microarray containing 5,011 recombinant human liver proteins and were able to identify three new antigens, RPS20, Alba-like and dUTPase, as highly autoimmune hepatitis-specific biomarkers [114].

Although these results are promising, the number of high-throughput genomic and proteomic studies in autoimmune liver diseases is still very limited.

Hepatocellular carcinoma

While beyond the scope of this review, there have been significant advances in early diagnosis, treatment and pathway analysis of HCC and hepatocarcinogenesis through genome, transcriptome and proteome high-throughput analysis, especially in the setting of liver cirrhosis. For more information on this topic we refer to recent reviews [116-118].

General conclusions and future directions

In the last decade, genomic and proteomic hypothesis-free studies have become increasingly common. Since liver fibrosis often takes many years to develop, and not every patient will become symptomatic, a method to select patients who will benefit from aggressive treatment in an early phase would be very beneficial. Therefore, there is a demand for biomarkers that can provide a prognostic indication for fibrosis, either in the natural course of chronic liver disease, or as a predictor of treatment response. Liver biopsy is currently the gold standard for follow-up in chronic liver disease, but it can have serious complications and suffers from sampling error and inter-observer variation. This drives the search for non-invasive direct or indirect biomarkers that correlate accurately with fibrosis stage.

Prospective predictive proteomic and genomic studies are difficult in liver disease, as follow-up is long, and biological samples can degrade over time. Thus far, many tests based on serum biomarkers correlate fairly well with the fibrosis stage when advanced fibrosis (METAVIR F3-4) is compared to mild or no fibrosis (F0 to 2), but lack resolution in the intermediate stages. Especially, these intermediate stages (F1 to 2) could be helpful in the early detection of progressive fibrosis and guide the hepatologist in treatment decisions. So far, genomic and proteomic studies for fibrosis staging have been mostly limited to viral hepatitis, with other diseases like alcoholic liver disease and NASH yet to be explored. Studying the fibrotic genome/proteome in these diseases will shed light on common and distinct pathological pathways leading to liver fibrosis.

Genomic and proteomic studies that have identified genes and proteins that correlate with fibrosis levels have yielded heterogeneous findings, most likely due to variations in sample preparations and patient populations/characteristics. The lack of standardized sample preparation protocols hinders reproducibility of protein spectra. A few gene and protein groups seem to correlate with fibrosis more consistently, mostly belonging to glutathione, oxidative stress, inflammatory and immune response pathways. For most of the identified proteins, adequate follow-up has been lacking so far, leaving scientists with lots of potential biomarker candidates still in need of validation.

Future high-throughput research will continue uncovering genes and proteins that can elucidate common and specific-disease pathways that lead to liver fibrosis. Standardization of sample preparation protocols should increase reproducibility of these studies, and will make it easier to select candidate genes and proteins that are suitable for validation as biomarkers for either fibrosis staging, or as predictive biomarkers for disease outcome and/or treatment response.

Abbrevations

2-DE/2D-PAGE: 2D-polyacrylamide gel electrophoresis; AIH: autoimmune hepatitis; ALD: alcoholic liver disease; BMC: bone marrow cell; CCl_4: carbon tetrachloride; CRS: Cirrhosis Risk Score; DIGE: gel electrophoresis; ESI: electrospray ionization; FACL4: fatty acid CoA ligase 4; FT-ICR: Fourier transform-ion cyclotron resonance; GWAS: genome-wide association studies; HCC: hepatocellular carcinoma; HCV: chronic hepatitis c viral infection; HSCs: hepatic stellate cells; IGFBP1: insulin-like growth factor binding protein 1; IMAC: immobilized metal affinity capture; ISGs: interferon-stimulated genes; iTRAQ: isobaric tags for relative and absolute quantitation; LC: liquid chromatography; MALDI: matrix-assisted laser desorption/ionization; MALDIMS: matrix-assisted laser desorption/ionization mass spectrometry; MS: mass spectrometry; m/z: mass-to-charge; NAFLD: non-alcoholic fatty liver disease; NASH: non-alcoholic steatohepatitis; OR: odds ratio; PBC: primary billiary cirrhosis; PCR: polymerase chain reaction; PKA: protein kinase A; Q-Q-TOF: second quadruple time-of-flight; Q-TOF: quadruple time-of-flight; RT-qPCR: reverse transcription quantitative PCR; SAGE: serial analysis of gene expression; SAM: significance analysis of microarray; SAX: strong anion exchange; SELDI: surface-enhanced laser desorption/ionization; SNPs: single nucleotide polymorphisms; STAP: stellate-cell activation-associated protein; SVR: sustained viral response; TAA: thioacetamide; TIMP-1: tissue inhibitor of metalloproteinases-1; TOF: time-of-flight; UPLC-ESI: ultra-performance liquid chromatography-electrospray ionization-tandem; WCX: weak cation exchange

STATE-OF-THE-ART PAPER

Genetics and Genomics of Stroke

Novel Approaches

Alison E. Baird, MBBS, PhD

Brooklyn, New York

Evidence for a genetic basis for stroke comes from twin and family studies and from the occurrence of a number of uncommon monogenic disorders, but the contribution of genetic factors identified for stroke so far is small. Advances in genetics and genomics may permit new insights. In recent genome-wide association studies, a number of single-nucleotide polymorphisms have been associated with specific stroke subtypes and major stroke risk factors such as diabetes and atrial fibrillation. These await replication. Studies of messenger ribonucleic acid expression have also shown promise for the development of genomic signatures for stroke classification. Stroke and coronary heart disease share some features of pathophysiology, risk, and treatment, and their genetic and genomic bases also appear to overlap. (J Am Coll Cardiol 2010;56:245–53) © 2010 by the American College of Cardiology Foundation

When the human genome was sequenced in 2003, the implications for cardiovascular and stroke medicine—in terms of the new diagnostic, therapeutic, and preventive strategies that may ultimately result—were immediately recognized (1,2). Genetic and genomic factors appear to contribute to all stages of the development of vascular disease, from predisposition, through risk and subclinical disease, to overt disease. Although the contribution of genetic factors identified for stroke is small at present, it is very possible that the sequencing of the genome may result in novel clinical applications, including the development of biomarkers for stroke.

Strokes result from focal reductions of blood flow to the brain and are second to coronary heart disease (CHD) in terms of vascular disease incidence, morbidity, and mortality. Currently, there are about 795,000 new and recurrent strokes per year in the U.S. compared with 1,350,000 new and recurrent coronary events (3). There is a substantial additional burden of asymptomatic cerebrovascular disease. About 83% of strokes are due to arterial vascular occlusion (ischemic stroke), and about 17% are due to vascular rupture (hemorrhagic stroke) (4–6).

Many scientific advances have occurred in stroke diagnosis, treatment, and prevention over the past 10 to 20 years (7,8), such as advances in neurovascular imaging and intravenous tissue plasminogen activator therapy, but important questions remain unanswered. Modifiable risk factors account for only about 60% of the population-attributable risk (PAR) for stroke (9,10), as opposed to risk factors identified for CHD, which may account for more than 90% of the attributable risk (11). The mechanisms for over 30% of ischemic strokes are not known, even after extensive workup (12–14). Stroke diagnosis is inaccurate in up to 30% of patients acutely, and it is not possible to reliably distinguish between ischemic and hemorrhagic stroke clinically. No blood-based diagnostic marker has yet been developed for stroke, unlike for acute coronary syndromes; this might be because of issues related to the blood-brain barrier. There is also no reliable way to predict which patients will develop hemorrhagic transformation in the brain after thrombolytic therapy (8).

This review begins with a description of the currently recognized genetic factors involved in stroke risk and etiology: family history, single-nucleotide polymorphisms (SNPs), and monogenic disorders. This is followed by the first results that have recently been obtained from genome-wide association and gene expression and protein expression profiling studies—new genomic methodologies that have been developed over the past decade (Online Appendix). The genetic and genomic overlap between stroke and CHD and other forms of vascular disease is becoming increasingly apparent, and some examples are provided in the final section.

Genetic Factors in Stroke Risk and Etiology

Genetic factors that are associated with increased stroke risk are a family history of stroke and a number of SNPs. A number of monogenic disorders cause stroke, either as a primary manifestation or a secondary manifestation. The contribution of these factors has been increasingly recognized over the past 10 to 20 years from findings in twin

---

From the Department of Neurology, SUNY Downstate Medical Center, Brooklyn, New York. The author has one patent relating to stroke and patents pending for intracerebral hemorrhage and vascular disease risk.

Manuscript received July 16, 2008; revised manuscript received February 2, 2010, accepted February 9, 2010.

Abbreviations and Acronyms

CADASIL = cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy

CHD = coronary heart disease

ICH = intracerebral hemorrhage

PAR = population-attributable risk

RNA = ribonucleic acid

SAH = subarachnoid hemorrhage

SNP = single-nucleotide polymorphism

studies (15) and the description of monogenic disorders such as cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL) (16). More recently, it was reported that Fabry disease accounts for a previously unrecognized proportion of strokes of undetermined mechanism (i.e., cryptogenic stroke) in the young (17). Evidence for a genetic basis for stroke has also come from experimental stroke models (18).

The importance of the accurate classification of stroke type and subtype needs to be appreciated, because ischemic and hemorrhagic strokes differ in their causes, pathophysiology, treatments, and outcomes (12,13) (Table 1). Careful classification of stroke type and subtype permitted the identification of genetic factors associated with CADASIL and with cerebral venous thrombosis (16,19).

Family history of stroke. In twin studies, the concordance rates for stroke are 17.7% in monozygotic twins and 3.6% in dizygotic twins (15,20). The heritability of stroke has varied in family studies, but allowing for some methodological weaknesses, it appears that a family history of stroke increases a subject's stroke risk by 2- to 3-fold (21,22). In the Framingham study, using information obtained across 3 generations, including the original and offspring cohorts, a parental history of stroke was associated with an approximately 2-fold increase in stroke risk: a paternal history of stroke was associated with a relative risk of 2.4 and a maternal history with a risk of 1.4 (21). In later studies looking at the heritability of stroke subtypes, the large artery atherosclerosis and small vessel subtypes were found to be more commonly inherited than the cardioembolic subtype (23).

Few studies have separated ischemic stroke risk from that of intracerebral hemorrhage (ICH), probably because of the smaller frequency of the ICH stroke type and the difficulty in retrospectively obtaining this information. It appears that ICH in a first-degree relative increases a subject's odds by as much as 2- to 6-fold (24). Subarachnoid hemorrhage (SAH) has a distinct clinical profile, and a family history of SAH has been associated with an increased risk for SAH of about 4-fold (25); because of this association, screening of first-degree relatives of patients with SAH is currently recommended (26). Evidence of a gene-environment interaction with smoking, another risk factor for SAH, also may exist for aneurysmal SAH (27).

Genetic polymorphisms. Polymorphisms in 2 genes increase the risk for cerebral venous thrombosis. A polymorphism in the gene coding for coagulation factor V results in a form of factor V variant, factor V Leiden, that is resistant to degradation by activated protein C, resulting in a hypercoagulable state (19). This polymorphism involves a single base pair substitution. The risk for cerebral venous thrombosis is increased almost 8-fold in subjects carrying 1 copy of the variant (28). The prothrombin G20210A polymorphism confers an almost 10-fold increased risk for cerebral venous thrombosis. The risk is further magnified with the use of the birth control pill and in the post-partum period (28). Both of these factors may be associated with a mildly increased risk for arterial ischemic stroke (19,28).

Monogenic disorders associated with stroke. These disorders are uncommon, accounting for <1% of all strokes. They are typically associated with stroke in childhood or young adulthood, with certain stroke types and subtypes, the absence of other stroke risk factors, and with specific phenotypes of the associated diseases (Table 2).

CADASIL was initially recognized in the 1990s as an adult-onset hereditary disorder of dementia and stroke (16), and its genetic and molecular basis was subsequently unraveled (Fig. 1). CADASIL is characterized by recurrent subcortical ischemic strokes starting at ages 30 to 40 years, progressive or stepwise cognitive decline, white matter changes on magnetic resonance imaging, and, in some patients, migraine with aura and mood disturbances (29,30). In addition to genetic analysis, skin biopsy is used to aid in diagnosis (31).

In other monogenic disorders—such as Fabry disease (X-linked recessive inheritance), sickle-cell disease (autosomal dominant inheritance), and mitochondrial myopathy, encephalopathy, lactic acidosis, and strokelike episodes—stroke is a secondary manifestation. In Table 2, monogenic disorders associated with stroke and vasculopathy are listed, along with disorders associated with premature atherosclerosis, arterial dissection, and monogenic forms of ICH. The reader is referred to several excellent reviews for specific details of these uncommon disorders (26,32,33).

Table 1 Major Stroke Types and Subtypes

Type	Subtype/Presumed Major Mechanism	Approximate Frequency (%)
Ischemic stroke		83
	Large artery atherosclerosis	14
	Cardioembolism	23
	Small-vessel disease	13
	Other determined	3
	Undetermined	30
Hemorrhagic stroke		17
Intracerebral hemorrhage	Hypertension	7
	Amyloid angiopathy	3
Subarachnoid hemorrhage	Intracranial aneurysm	7
Cerebral venous thrombosis		<1

The TOAST (Trial of Org 10172 in Acute Stroke Treatment) subtypes are commonly used to classify ischemic stroke (14). Common subtypes of hemorrhagic stroke are intracerebral hemorrhage and subarachnoid hemorrhage. A minority of strokes result from vascular occlusion in the cerebral venous system, termed cerebral venous thrombosis (4–6).

Table 2 Monogenic Disorders Associated With Stroke

Disorder	Causative Gene/Chromosome Location	Inheritance Pattern
Small-vessel vasculopathy		
CADASIL	Notch 3 gene	AD
CARASIL	Unknown	AR
HERNS	3p21.1-p21.3	AD
Small-artery and large-artery vasculopathy		
Fabry disease	Alpha-galactosidase A gene	XL-R
Pseudoxanthoma elasticum	ATP-binding cassette subfamily C member 6 gene	AR or AD
Large-artery vasculopathy		
Moyamoya disease	3p24.2-26, 17q25	Polygenic or AR
Premature atherosclerosis		
Homocystinuria	Cystathionine beta synthase	AR
Arterial dissection		
Ehlers-Danlos syndrome type IV	Collagen type III gene	AD
Marfan syndrome	FBN1 and TGFβR2 genes	AD
Inherited cerebral amyloid angiopathies		
Hereditary cerebral hemorrhage with amyloidosis of the Dutch type	Amyloid precursor protein gene	AD
Cystatin C–related familial cerebral amyloid angiopathy	Cystatin-C gene	AD
Familial amyloid polyneuropathy	Transthyretin gene	AD
Cerebrovascular malformations		
Autosomal dominant polycystic kidney disease	PKD1, PKD2	AD
Cerebral cavernous malformations	7q21-q22, 7p13-p15, 3q25.2-q27	AD or sporadic
Hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu disease)	Endoglin and activin receptor–like kinase 1 genes	AD

Further details may be found in Meschia et al. (26), Ballabio et al. (32), and Rost et al. (33).

AD = autosomal dominant; AR = autosomal recessive; ATP = adenosine triphosphate; CADASIL = cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy; CARASIL = cerebral autosomal recessive arteriopathy with subcortical infarcts and leukoencephalopathy; FBN1 = fibrillin 1; HERNS = hereditary endotheliopathy with retinopathy, nephropathy, and stroke; PKD = polycystic kidney disease; TGFβR2 = transforming growth factor, beta receptor II; XL-R = X-linked recessive.

Genomewide Association Studies

As a result of the sequencing of the human genome, genomewide association studies may permit the detection of common variant alleles (>5%) of mild to moderate effect (34,35) associated with common disorders such as stroke. It is currently believed that common stroke may result from a number of genes of modest effect that in combination exert a significant effect on stroke risk (36). Commercial arrays containing a huge number of SNPs are now available, but the power of a typical study of several thousand patients is of the order of only 10% to 25% (34,35), so it is most important that adequate sample sizes be studied and that notable findings be validated and replicated in independent cohorts. Significant amounts of time, energy, and resources were expended in linkage studies and association studies of candidate genes over the past decade (37,38); many early findings turned out to be false positives, with studies often being limited by insufficient sample sizes.

The first genomewide association study in stroke was reported from the ISGS (Ischemic Stroke Genetics Study) in 2007 (39). No genetic locus was specifically and robustly associated with stroke, but there were only about 250 patients and controls. This group went on to study the 9p21.3 region (i.e., a region on the short arm [p] of chromosome 9) that had already been associated with CHD (40,41). An association was found with stroke, although it was not determined by genotyping that this association involved the same variants (40). Another group has since described modest associations between variants in the 9p21 region (rs2383207 and rs10757274) and ischemic stroke (42). However, in another study, 6 SNPs in the 9p21 region (including rs2383207) were found to be associated with the large artery atherosclerotic subtype of ischemic stroke, independent of CHD and vascular risk factors (43). The lead SNP, rs1537378, had a pooled odds ratio for stroke of 1.21 and a point estimate of the PAR for atherosclerotic ischemic stroke of 20.1% (43).

In a case-control study reported in 2008 (44), the 4q25 region was found to be associated with the cardioembolic subtype of ischemic stroke (with an odds ratio of about 1.5). This locus had already been found to be associated with atrial fibrillation. An association, although to a lesser degree, was found with all ischemic stroke (44); this latter finding was attributed to possible undetected cases of atrial fibrillation in patients with cryptogenic strokes. Another locus for cardioembolic stroke, on 16q22, has been recently reported (45). These studies demonstrate the value of having accurate stroke subtype classification, although having a standardized methodology in multicenter studies is a major challenge. For intracranial aneurysms, initial and seemingly quite robust associations have been found with loci on 2q, 8q, and the 9p21 region (the rs10757278 variant that is also associated with CHD) (46,47).

The first prospective genomewide association study in stroke was reported in 2009 from the CHARGE (Cohorts for Heart and Aging Research in Genomic Epidemiology)

Leukoencephalopathy

Figure 1 **Pathophysiology of CADASIL**

Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL) is an autosomal dominant disorder resulting from a number of mutations in the Notch 3 gene. This gene is located on chromosome 19, on the p (short) arm, at 19p13.2 to p13.1. This gene has 33 exons; the majority of mutations occur on exons 2 to 6 and are single-point or missense mutations. There is an accumulation of osmophilic granules in smooth muscle of blood vessels throughout the vasculature, particularly in the brain, the retina, and the skin.

Consortium (48). Consisting of 4 prospective epidemiological cohorts, this large study of nearly 19,600 subjects with 1,544 incident strokes identified 2 SNPs on chromosome 12, in the region of 12p13, although replication was obtained only for the rs12425791 SNP; the hazard ratios were 1.3 for all stroke and 1.0 for ischemic stroke. This SNP was located close to the ninjurin 2 gene, which encodes an adhesion molecule expressed in glia that shows increased expression after nerve injury. Without genotyping, it is not known if this finding is associative or causative. The International Stroke Genetics Consortium, established in 2007, is currently validating the results of the CHARGE study. The International Stroke Genetics Consortium is also collaborating with the Wellcome Trust Case Control Consortium–2 in a multistage genomewide association study of ischemic stroke. Plans are under way for the development of a similar genomewide survey in the U.S. (49).

Aside from unaccounted stroke risk, genomewide association studies may reveal genetic bases for major stroke risk factors themselves, which account for up to 60% of the PAR for stroke (9,10,50) (Fig. 2). These include hypertension (the leading modifiable stroke risk factor), which has a PAR of 30% to 40%; diabetes; smoking; atrial fibrillation; and CHD itself (with a PAR of about 4% to 5%). Loci have been associated with atrial fibrillation (4q25 and 6q22) (44,45), diabetes (loci in and around the genes cyclin-dependent kinase inhibitor 2A and cyclin-dependent kinase inhibitor 2B in the 9p21 region, among others) (51), and hypertension (serine threonine kinase 39) (52).

There has clearly been a remarkable amount of information coming to light, and a number of loci of interest are emerging, but it is too early to tell how major an impact genomewide association studies will turn out to have. In studies of other disease states, the functions of some genes have not conformed to known disease biology or not coded for proteins, as expected, but rather for ribonucleic acids (RNAs), highlighting the importance of gene expression and of micro-RNAs as future players (34–36). It is also vital that these findings be replicated and that their PARs be evaluated further; loci found for some other disease states have been of very small effect or have had little predictive value after adjustment for known risk factors (36), as may be the case for the rs10757274 polymorphism on chromosome

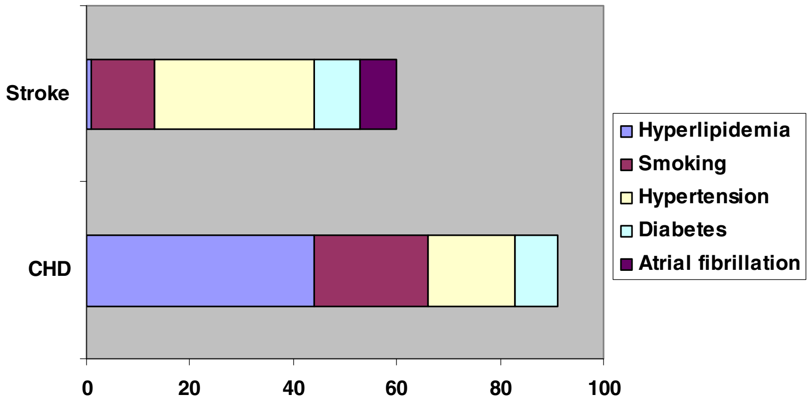

Figure 2 **Attributable Risks of Major Risk Factors for Stroke and CHD**

Vascular disorders, such as coronary heart disease (CHD) and stroke, share a number of risk factors in common. CHD also accounts for 1% to 2% of the population-attributable risk for stroke. Data were obtained from the INTERHEART (Effect of Potentially Modifiable Risk Factors Associated With Myocardial Infarction in 52 Countries) study (11) using Northern American statistics and data from current guidelines for primary prevention of stroke (50).

9p21.3 and prediction of CHD risk (53). In the future, it is likely that the focus will be on genotyping studies to look for less common variant alleles of more significant effect and in studying copy number variants as additional genetic factors associated with common disorders such as stroke.

Gene Expression Profiling, Proteomics, and Metabolomics

A number of important methodologies and technologies have been developed in tandem to those for investigating deoxyribonucleic acid variations, based on the fact that deoxyribonucleic acid is transcribed to messenger RNA, which in turn is translated into protein and metabolites. These methods can be used to investigate the entire transcriptome (gene expression profiling or RNA expression profiling), the proteome (proteomics), and the metabolome (metabolomics). They capture not only functional changes induced by genetic variations but also changes induced by environmental factors, risk factors, and the effects of interventions, and they can be used to monitor functional changes occurring over time. The interest of these methods for stroke is that they offer potential for identifying biomarkers (e.g., from the blood) that can be used in the clinic to diagnose and monitor disease and changing risk associated with mutations and treatment interventions. In genome-wide association studies, they are used to study if and to what degree genetic polymorphisms are functional.

Gene expression profiling and signatures for stroke classification. Gene expression profiling has been most widely applied in the field of oncology. Preliminary studies have been performed in carotid plaque specimens removed during endarterectomy (54).

Messenger RNA profiling of the peripheral blood has also been used to investigate a number of neurological disorders, including stroke, despite initial concerns over the specificity of signatures obtained. Blood-derived mononuclear cells (monocytes and lymphocytes) are involved in the development of atherosclerotic lesions associated with many forms of vascular disease, including stroke (55). In stroke, peripheral blood mononuclear cells are also of significance because blood-borne leukocytes, first polymorphonuclear cells and then subsequently mononuclear cells, are key players in the evolution of brain infarcts. The cells selectively migrate to and infiltrate the ischemic brain tissue. These inflammatory and immune cells may not only exacerbate ischemic reperfusion injury but may also be involved in tissue repair and remodeling after stroke (56). Changes in functional gene expression in peripheral blood mononuclear cells in brain disorders may occur in response to exposure to brain antigens (57).

Early human studies in stroke using oligonucleotide microarrays have been promising. Using peripheral blood mononuclear cells, a validated and replicated gene expression signature of ischemic stroke within the first 72 h has been identified (58). The gene expression changes seemed to reflect an adaptive response, at least in part, to the ischemic stroke, with up-regulation of genes involved in cell adhesion, inhibition of neuronal apoptosis, response to hypoxia, and vascular repair (Table 3). One example is ectonucleoside triphosphate diphosphohydrolase 1 (cluster of differentiation 39), a prominently up-regulated gene that is of interest for its cerebroprotective and cardioprotective properties. A panel of 22 genes was about 80% accurate for the detection of ischemic stroke in an external sample (58), while another group found this panel to be over 85% accurate, using whole-blood profiling (59). Signatures have since been developed for ICH (60) (prominently up-regulated genes being amphiphysin and interleukin-1 receptor 2), stroke recovery (61), and ischemic stroke subtypes (62).

Given the increasing recognition of the role of lymphocytes in stroke and vascular disease (63), and the improved charac-

Table 3 Classes of Genes Expressed in Peripheral White Blood Cells in Ischemic Stroke

Pathophysiological Class	Examples
White cell activation and differentiation (65%)	
	Toll-like receptor 2
	Ectonucleoside triphosphate diphosphohydrolase 1 (CD39)
	CD14
	Interleukin-13 receptor, alpha 1
	FcGR2A
Response to hypoxia (15%)	
	Adrenomedullin
	Leukotriene A4 hydrolase
	Cytochrome b-245
Vascular repair (10%)	
	CD36 antigen (thrombospondin receptor)
	Thrombomodulin
Response to the altered cerebral microenvironment (5%)	
	Neuronal apoptosis inhibitory protein (apoptosis inhibition)
	Catechol-O-methyl transferase (neurotransmitter degradation)
	Glutamine ligase (neurotransmitter degradation)
	Sortilin (neuronal apoptotic cell death)
	Phospholipid scramblase 1 (neurite outgrowth in neural development)
	Growth arrest specific 7 (neurite outgrowth)
Unknown (5%)	
	KIAA0146 protein

Classes of genes showing increased expression in peripheral blood mononuclear cells in the first 72 h of ischemic stroke (58). These changes were suggestive of at least a partial adaptive response to the stroke.

CD = cluster of differentiation; FcGR2A = Fc fragment of IgG, low affinity IIa, receptor.

terization of lymphocyte subpopulations, ongoing studies are investigating gene expression within leukocyte populations, along with circulating stem cells that may be involved in tissue repair and recovery after stroke. Real-time polymerase chain reaction studies are proving practical in ongoing application and validation studies. This approach offers hope for the development of a rapid diagnostic test for stroke if a suitable technology platform could be identified. This work also offers hope for the identification of gene panels for vascular disease risk and for prediction of response to treatment.

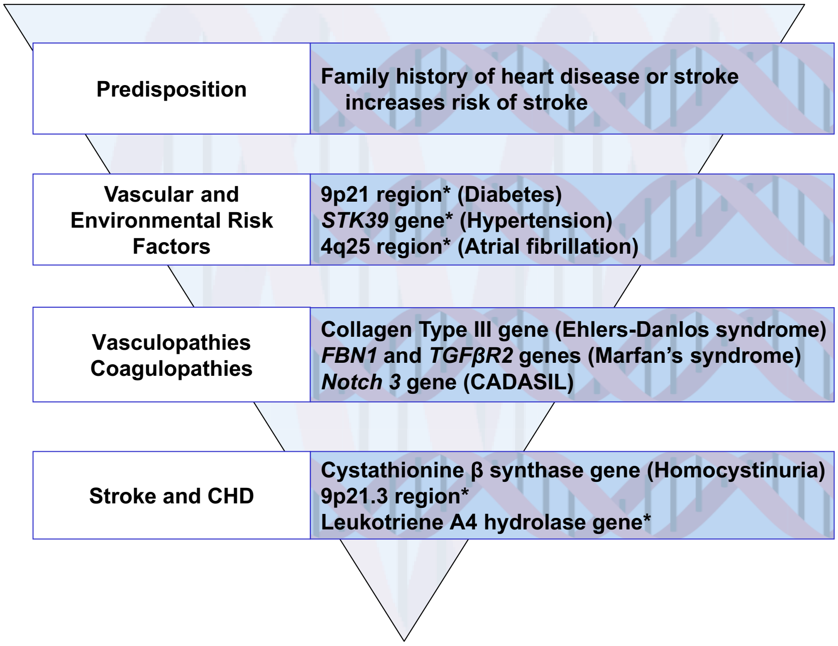
Proteomics and metabolomics. Blood-based protein biomarkers (64) could be of great value for the early detection of stroke because they could permit more accurate diagnoses to be made at the initial point of care. Currently, stroke evaluation is dependent on the patient's being taken to the hospital and undergoing a brain scan, which can delay the commencement of therapy for up to 60 to 90 min. Using a candidate protein approach, a panel of 4 proteins showed modest accuracy for the diagnosis of acute ischemic and hemorrhage stroke (65). The proteins were a marker of glial activation (S100beta), a marker of inflammation (matrix metalloproteinase-9), brain natriuretic factor, and D-dimer. Using surface-enhanced laser desorption/ionization technology, apolipoprotein C-I and apolipoprotein C-III were identified as potential plasmatic markers to distinguish between ischemic and hemorrhagic stroke (66). The results were validated using enzyme-linked immunoabsorption assays; further findings on clinical utility are awaited.

In another study that used surface-enhanced laser desorption/ionization and logical analysis-of-data classification modeling, 3 biomarkers were identified from mass spectral peaks that could detect ischemic stroke with an accuracy of 75% (67). The results were upheld in a validation sample, although the proteins were not definitively identified. The correlation and root mean absolute error of the logical analysis-of-data predictive model were superior to those of the other statistical algorithms used. Metabolomics has not yet been applied to stroke.

Pharmacogenomics. Pharmacogenomic approaches have included the evaluation and identification of genetic modifiers of clinical responses to warfarin, the statin drugs, clopidogrel, and antihypertensive therapy (68). The goals of these approaches are to personalize dosing and to minimize side effects.

Heart–Brain Linkages

Coincident with the aforementioned findings of genetic loci and gene expression changes of interest in stroke have been dramatic advances in the genetics of heart and vascular disease. A number of genetic and genomic factors already appear to overlap between stroke and heart and vascular disease, contributing to all stages of disease development: familial predisposition (21,22), vascular risk, monogenic vasculopathies, and in genomewide association studies, for example, variants in and around the 9p21 region, as previously described, and the leukotriene pathway (58,69) (Fig. 3). These



Predisposition
Family history of heart disease or stroke increases risk of stroke
Vascular and Environmental Risk Factors
9p21 region* (Diabetes)
STK39 gene* (Hypertension)
4q25 region* (Atrial fibrillation)
Vasculopathies
Coagulopathies
Collagen Type III gene (Ehlers-Danlos syndrome)
FBN1 and *TGFβR2* genes (Marfan's syndrome)
Notch 3 gene (CADASIL)
Stroke and CHD
Cystathionine β synthase gene (Homocystinuria)
9p21.3 region*
Leukotriene A4 hydrolase gene*

Figure 3 **Stroke and Heart and Vascular Disease: Genetic and Genomic Links**

Common genetic and genomic factors appear to contribute to the development of vascular disease, including familial predisposition, risk factors, subclinical disease, and overt clinical disease. Some are proven and some are putative **(*)**, having been recently reported in genomewide association studies. CADASIL = cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy; CHD = coronary heart disease; FBN1 = fibrillin 1; STK39 = serine threonine kinase 39; TGFβR2 = transforming growth factor, beta receptor II.

are deserving of further study. Furthermore, the vasculopathy of CADASIL has not been thought to involve the heart, but in 1 series, high rates of myocardial infarction were reported in patients with CADASIL (70). Higher rates of sudden unexplained death in patients with CADASIL have also been reported and have been suggested to be due to autonomic derangement, placing patients at higher risk for life-threatening arrhythmias (71).

Conclusions

At present, the contribution of genetic factors in stroke is small, involving familial predisposition, a small number of monogenic disorders such as CADASIL, and polymorphisms associated with cerebral venous thrombosis. New associations are now being reported in genomewide association studies, but these need confirmation. Future work may well focus on genotyping, looking for rarer high-risk variant alleles and studying copy number variants. It is especially important that initial results from expression profiling of peripheral blood leukocytes be further explored. Genomic methods already show particular promise for improving stroke classification. They could ultimately permit the development of biomarkers that could be valuable for the diagnosis, treatment, management, and assessment of not only stroke but many other vascular disorders.

Abstract: Glioblastoma (GBM) is the most aggressive form of brain cancer, with a dismal prognosis and extremely low percentage of survivors. Novel therapies are in dire need to improve the clinical management of these tumors and extend patient survival. Genetic therapies for GBM have been postulated and attempted for the past twenty years, with variable degrees of success in pre-clinical models and clinical trials. Here we review the most common approaches to treat GBM by gene therapy, including strategies to deliver tumor-suppressor genes, suicide genes, immunomodulatory cytokines to improve immune response, and conditionally-replicating oncolytic viruses. The review focuses on the strategies used for gene delivery, including the most common and widely used vehicles (*i.e.*, replicating and non-replicating viruses) as well as novel therapeutic approaches such as stem cell-mediated therapy and nanotechnologies used for gene delivery. We present an overview of these strategies, their targets, different advantages, and challenges for success. Finally, we discuss the potential of gene therapy-based strategies to effectively attack such a complex genetic target as GBM, alone or in combination with conventional therapy.

Keywords: gene therapy; oncolytic virus; stem cells; nanotechnology; gene transfer; glioma invasion; suicide gene; immunomodulation

1. Introduction

Glioblastoma (GBM) is the most aggressive tumor of the Central Nervous System (CNS) and its prognosis is one of the worst among all cancer types. Although the number of GBM cases is small compared to other solid tumors, population statistics still reveal a dim picture after years of research and improvement in the clinical management of this disease [1]. Of the approximately 13,000 new patients diagnosed with GBM in the US every year, almost 50% of the patients die within one year and 90% within three years following diagnosis [2], causing more years of life lost than most types of cancer [3].

GBM is therefore considered a fatal malignancy, incurable by conventional therapeutic strategies [4]. A major factor that contributes to the dismal prognosis of GBM is the physical and physiological isolation of these tumors within the CNS, which makes difficult the delivery of chemotherapeutics. In addition, the CNS is largely regarded as an immune sanctuary protected from systemic immune responses, therefore facilitating immune evasion of tumor cells and limiting the efficacy of systemic immune-boosting approaches. A third and critical factor that makes these tumors extremely difficult to eradicate is the highly invasive nature of GBM cells, which disperse along blood vessels and white matter, resulting in a disseminated disease that is impossible to completely resect [4]. Finally, the presence of a disseminated tumor stem-like cell population that supports tumor self-renewal and is particularly resistant to chemo- and radio-therapy, is another major factor underlying tumor recurrence and poor long-term survival [5].

Given the resistance of these tumors to conventional therapeutic approaches there is an urgent need to develop alternative strategies to complement or improve current approaches and improve long-term patient survival. Strategies under development include novel adjuvant chemotherapeutics to be combined with standard care, as well as novel molecularly-targeted approaches against the tumor and its microenvironment. In this review we will focus on a host of molecularly-targeted approaches collectively aggregated under the concept of *gene therapy*.

Gene "therapy" as the possibility of selecting the genetic information of organisms was first mentioned even before the identification of DNA as genetic material [6], but the formal concept of gene therapy as horizontal transfer of genetic material with the potential to treat diseases only solidified in the early 1970s [7], when technological advances allowed researchers to deliver tailored genetic material to mammalian cells. "Strict" gene therapy is based on the ability to replace a defective gene function through delivery and integration of the functional version of the gene. Therefore, gene therapy strategies have largely been developed for genetic diseases with clear dependency on a single gene deficiency [8], such as recessive enzymatic deficiencies and blood disorders.

Despite being a genetic disease, the possibility of applying strict gene therapy for cancer is less straightforward since tumors develop through multiple known and unknown genetic abnormalities. Moreover, the accumulation of mutations and evolution of the tumor's genetic makeup during malignant progression make cancers a genetic moving target that would defeat the single gene-replacement approach. Therefore, the concept of gene therapy for cancer has been widened to encompass the general delivery of therapeutic genetic material to the tumor, to kill cancer cells or enhance the immune response against them.

Strategies for gene therapy of cancer in general, and gliomas in particular, have been in development for the past twenty years, with a strong record of success in pre-clinical models and an increasing number of models reaching clinical trials [9] (see Table 1 for a summary of active trials). Major approaches employed for gene therapy of GBM have included: (1) delivery of suicide genes to convert prodrugs in the tumor and achieve tumor cell death; (2) delivery of cytokine genes to activate and attract immune cells against the tumor; (3) delivery of tumor-suppressor genes to reprogram tumor cells into apoptosis; and (4) delivery of conditionally-replicating viruses to specifically lyse tumor cells while sparing normal tissue. Carriers of genetic material have usually been viruses, but alternative vehicles such as stem cells, nanoparticles and liposomes, have also been extensively developed and reached the clinical stage. The following sections will describe these approaches in detail, comparing the advantages and specific challenges faced by each one. A summary of these strategies and examples of representative genes employed are shown in Figure 1.

Abbreviations: AdV, adenovirus; CDA, cytosine deaminase; CED, convection-enhanced delivery; CMV, cytomegalovirus promoter; Flt3L, FMS-like tyrosine kinase 3 ligand; TK, thymidine kinase; *: E.A.C. is currently involved in these two active (non-recruiting) clinical trials.

Figure 1. Different strategies for gene therapy of GBM. (**A**) Suicide genes: GBM cells receive the suicide gene by local injection of a carrier, together with systemic delivery of a prodrug (1). The suicide gene converts the prodrug into a cytotoxic product (2) that kills the recipient cell and non-transduced bystander tumor cells (3); (**B**) Immune activation: The gene for an immunomodulatory cytokine is delivered to the tumor cells using several possible vehicles with tumor tropism (1), including viruses or stem cells. Cytokine expression increases tumor cell apoptosis (2) and activates immune cells such as macrophages, natural killer cells or T-cell lymphocytes (3); (**C**) Oncolysis: The tumor is infected with conditionally-replicating oncolytic viruses (1) that lyse the tumor cells (2–3) while sparing normal ones; (**D**) Reprogramming: Tumors receive the functional copy of a tumor suppressor gene (1), which subsequently induces cell cycle arrest or apoptosis (2).

cellular carrier (NSN, MSC)
secreted cytokines
conditionally replicating virus
carrier with tumor suppressor gene
non-functional tumor suppressor
macrophages
T lymphocytes
NK lymphocytes

2. Virus-Based Gene Therapy of GBM

Viruses targeting mammalian cells have evolved as effective vehicles for horizontal gene transfer and have therefore been the preferred approach for gene therapy since its beginnings [7]. Moreover, the specific neurotropism of certain herpesviruses, adenoviruses and paramyxoviruses [12–16] has made them particularly valuable to target cells of the neural lineage, including malignant brain tumor cells. The first attempt to treat gliomas with a non-engineered virus was an unsuccessful study using attenuated mumps virus, conducted in 1982 [17]. A decade later, two improved strategies using engineered viruses were described almost simultaneously: the use of transduced cells delivering engineered retroviruses into the tumor stroma [18,19], and the first use of an engineered Herpes simplex virus (HSV) for selective replication in glioma cells [20]. This research marked the beginning of two of the major strategies used in glioma virotherapy: (a) targeting the tumor with replication-deficient viruses carrying conditionally-expressing suicide genes; and (b) using tumor-specific, replication-competent oncolytic viruses. The following sections describe the major strategies that have been employed for GBM gene therapy using viruses and their current pre-clinical and clinical status.

2.1. Viral Delivery of Suicide Genes

Systemic chemotherapy of tumor cells is usually limited by toxic side effects caused on dividing normal cells. Suicide gene therapy was envisioned as a way to overcome this limitation, and is based on the systemic delivery of an inactive prodrug together with tumor-specific expression of a drug-activating enzyme (the *suicide gene*) [21,22]. Suicide genes are usually absent or expressed at very low levels in mammalian cells [23] and are therefore delivered using a viral transduction system [9].

The best studied suicide gene is the HSV-derived enzyme Thymidine Kinase (HSV-TK) [9,24,25]. This enzyme catalyzes the phosphorylation of cytotoxic nucleoside analogues that can be incorporated into the DNA of actively proliferating cells, disrupting DNA replication and halting cell division. Since the prodrug nucleosides are poor substrates for mammalian TK, the toxic effect can be restricted to actively dividing cells that have been transduced with HSV-TK using non-replicating herpesvirus or adenovirus [9,23]. This strategy was first used by Ezzedine and colleagues in 1991 to demonstrate the selectivity and efficacy of HSV-TK to kill subcutaneously-implanted glioma cells upon administration of the prodrug ganciclovir [26]. Improvements of this strategy have included the use of different drug formulations to enable sustained intratumoral drug delivery [27] and the use of mutant HSV-TK versions that confer increased sensitivity to the antiviral prodrugs [25,28].

An added advantage of suicide gene therapy is the spread of cytotoxicity from the originally infected cells to neighboring neoplastic, non-infected cells, an effect known as *bystander cytotoxic effect* [22,29,30]. In the case of TK, however, the bystander effect is somewhat limited because phosphorylated nucleoside analogues do not cross the cell membrane. Instead, they must be transferred to the neighboring cells via gap-junctions or by release of apoptotic vesicles from the infected, dying cell [31–33].

In spite of the initial promise of suicide gene therapy for glioma, further evidence suggested that even HSV-TK expressing cells could become resistant to the prodrugs, therefore requiring combination of this molecularly-directed gene therapy with conventional chemo-radiotherapy [25,28,34–36].

There has also been concern about possible toxic effects, poor rate of delivery of HSV-TK to the tumor cells [37], and immune response against the delivery vehicle. For example, non-human primates treated with adenovirus-delivered HSV-TK showed dose-dependent toxicity and developed antibodies against the viral particles [38]. Chronic inflammatory symptoms (including macrophage activation and lymphocyte infiltration) were also observed in the brain of long-term surviving rats that had been implanted with intracranial gliomas and treated with adenovirus-delivered HSV-TK [39]. Despite these caveats, viral-delivered HSV-TK has proven to be a safe strategy in multiple phase I and II clinical trials [40–42] and continues to be the most common suicide gene approach in active trials (see Table 1 for active clinical trials). Side effects have been fairly minimal and the major limiting factor has not been toxicity but lack of significant improvement in efficacy against placebo. This was demonstrated in a large, multicenter, phase III clinical trial for HSV-TK (GLI328 International Study Group) that employed retrovirus-producing cells to deliver HSV-TK gene therapy in patients with newly-diagnosed GBM [37]. The trial reported a good safety profile for this adjuvant treatment, although there were no significant improvements in progression-free or overall survival. This lack of effect was largely attributed to poor distribution of the carrier and limited delivery of HSV-TK into the tumor.

Another widely studied suicide gene is the bacterial enzyme Cytosine Deaminase (CDA), which converts the prodrug 5-fluorocytosine to the toxic compound 5-fluorouracil (5-FU). 5-FU can be further converted to 5-fluorouracil triphosphate, which interferes with RNA processing, or 5-fluorouridine-5'-monophosphate, which irreversibly inhibits DNA synthesis [23]. Importantly, 5-FU can diffuse to neighboring cells and achieves bystander cytotoxic effect that does not require the presence of physical cell-cell contacts [21,43]. Further enhancement of cytotoxicity has been achieved by using an engineered bacterial CDA (bCDA-Asp^{314}Ala) with increased affinity for 5-fluorocytosine. Combination of this recombinant CDA with radiotherapy has shown significant tumor cell killing and delayed tumor growth in xenograft models of glioma [23]. Adenovirus-delivered CDA has also been combined with a second enzyme, Uracil Phosphoribosyl Transferase (UPRT), which catalyzes the conversion of 5-FU into 5-fluorourydine-5'-monophosphate. Simultaneous expression of CDA and UPRT genes has shown cooperative antitumor effects [41]. Interestingly, the sensitivity of glioma cells to the combination of CDA and UPRT plus systemic 5-fluorocytosine seemed to be p53-dependent [44], suggesting that p53 status could be used as stratification criteria for this treatment. Viral-delivered, CDA-based therapy has reached the clinical stage and a non-lytic, replicating retroviral vector (Toca-511) [45] is currently being tested in a phase I/II clinical trial to deliver the enzyme in combination with 5-fluorocytosine in patients with recurrent high-grade glioma (NIH trial NCT01156584, Table 1).

A third example of nucleoside-modifying suicide gene therapy is the use of *E. coli*-derived Purine Nucleoside Phosphorylase (PNP), which can convert non-toxic adenosine ribonucleosides (e.g., fludarabine) into toxic adenine analogs (2-fluoroadenine) that disrupt RNA processing. These metabolites can diffuse to neighboring cells, resulting in robust bystander effect in proliferating and non-proliferating cells [46,47]. Retrovirus-carried PNP has been shown to integrate in the host cell DNA, leading to long-term effect of this treatment *in vivo* [47]. An important development of this approach was the combination of herpesvirus-delivered PNP with antibiotics to remove intestinal flora that could convert the prodrug outside the tumor. This approach allowed the use of lower doses of the cytotoxic agent, enhancing chemoprotection and efficacy in a mouse model of glioma [48].

Nucleic acid-targeting gene therapies have also used transgenes coding for enzymes that generate DNA-alkylating compounds. This strategy has a considerable advantage because cytotoxicity does not depend on DNA replication or RNA expression, therefore killing both proliferating as well as quiescent glioma cells. An example of pro-alkylating suicide gene that has been tested in several solid tumor models is the bacterial enzyme carboxypeptidase G2 (CPG2). When combined with nitrogen mustards prodrugs (such as 4-[(2-chloroethyl)(2-mesyloxyethyl)amino]benzoyl-L-glutamic acid (CMDA) or ZD2767P), CPG2 yields mustard-like compounds that crosslink DNA [49]. This conversion is specific to CPG2, which has no mammalian homologues, therefore preventing non-specific generation of highly toxic alkylating compounds in off-target tissues. Engineering of this enzyme for cell-surface expression has been used to enhance the bystander effect of prodrugs that cross the cell membrane poorly and do not reach therapeutic effect with intracellular CPG2 [50]. Although CPG2 has not been tested in gliomas *in vivo*, it has been delivered to cultured glioma cells using replication-deficient adenoviruses and shown cytotoxicity comparable or higher than HSV-TK in the same cells [51].

One extensively studied pro-alkylating suicide gene therapy has used cytochrome P450 (*CYP2B1* gene), the only example of a mammalian-derived suicide gene. This cytochrome can hydroxylate the immunomodulatory prodrug cyclophosphamide (CPA), generating an alkylating phosphoramide mustard. The first demonstration of this strategy for gliomas *in vivo* used fibroblasts transduced with a replicating retrovirus carrying CYP2B1, which were injected intratumorally in mice carrying intracranial GBM xenografts [52]. Following intrathecal administration of CPA, this study demonstrated partial regression of the intracranial tumor mass and limited or absent tumor dispersion to the meningeal space. Further development of this strategy placed the CYP2B1 gene in a replicating HSV (see description of oncolytic HSV in Section 2.5), showing strong antitumor effect when CPA chemotherapy was combined with HSV-mediated tumor oncolysis [53]. A significant advantage of CPA is the inhibitory effect of this drug on the innate immune activity against HSV, therefore reducing viral clearance and enhancing both gene delivery and viral oncolysis [54].

Finally, it should be noted that the concept of suicide genes can be expanded to include additional examples of cytotoxic genes as long as they are specifically delivered to and active in the target tumor cells. One example is the potent *Pseudomonas* exotoxin A, a cytotoxin produced by *Pseudomonas aeruginosa* that disrupts protein synthesis. A truncated form of this toxin conjugated to mutated interleukin IL-13 (mhIL-13-PE, marketed under the name Cintredekin Besudotox) specifically binds and kills glioma cells while sparing normal neural cells that lack the glioma-specific receptor for the interleukin (IL13Rα2) [55]. In an elegant development of this strategy, an adenoviral vector was developed for conditional expression of mhIL-13-PE in transduced glioma cells [56]. The vector also expressed IL-4 to saturate the normal receptor of IL-13 (IL4R/IL13R), therefore preventing binding of the chimeric toxin to normal neural cells and achieving specific cytotoxicity. Inoculation of this virus in multiple models of intracranial glioma using athymic and immunocompetent mice resulted in significant tumor toxicity and increased animal survival with high proportion of long-term survivors [56].

2.2. Viral Delivery of Tumor-Suppressor Genes

Tumor suppressor genes are major regulators of DNA repair, cell proliferation, and apoptosis. Deletions and inactivating mutations in those genes are common in all cancers, including gliomas. In particular, mutations in three pathways containing tumor suppressors are commonly associated with high-grade human gliomas: p53/MDM2, p16/Rb, and PTEN [57]. Based on this feature of brain tumor biology, viral strategies have been designed in an attempt to reprogram tumor cells by restoring tumor suppressor activity in cells carrying inactivating mutations in those genes.

p53 is considered one of the most critical mediators of growth arrest and apoptosis in response to DNA damage, hypoxia, and growth factor withdrawal. This is one of the most frequently mutated genes in gliomas, being inactivated in about 30% of primary and 65% of secondary GBMs [58]. Tumor suppressor therapy using p53 in glioma cells was first attempted by delivering this gene, under control of the potent CMV promoter, using non-replicating adenovirus serotype 5 (Ad5CMV-p53). Restoration of the functional gene induced robust apoptosis of the infected cells *in vitro* and reduced tumorigenesis *in vivo* [59]. However, inoculation of the same vector in GBM-bearing mice was insufficient to reduce intracranial tumor growth [60], possibly due to poor gene transfer in established tumor tissue. Interestingly, adenoviral transduction of p53 into wild type p53-bearing glioma cells has also shown marginal [59–61] to robust [62] inhibition of cell proliferation and induction of apoptosis, indicating that these effects are not solely dependent on the restoration of a functional copy of p53.

Limitations of tumor suppressor-based gene therapy have included poor gene transfer as mentioned, lack of bystander effect, and potential resistance arising from the inherent genetic heterogeneity within GBM. However, transduction of tumor suppressor genes such as p53 may present an excellent opportunity for combinatorial therapy since they could re-sensitize the cells to radiation and chemotherapy [59,61,63,64] or reduce immune evasion when combined with immune-boosting strategies [65]. Successful pre-clinical results with p53-restoration led to a phase I clinical trial of Ad5CMV-p53 (INGN 201) for recurrent malignant glioma, involving injection of the virus pre- and post-resection. Exogenous p53 protein was found in the nuclei of tumor cells in all patients treated with this strategy, although transduced cells were found only within a short distance from the injection site. Adverse events were minimal and the trial tested doses up to 3×10^{12} plaque-forming units (p.f.u.) without reaching maximum tolerable dose [66].

$p16^{INK4A}$ is another major tumor suppressor that causes cell cycle arrest at the G1-S transition point by maintaining hypo-phosphorylated status in the Retinoblastoma protein (Rb) [59,60]. Adenoviral-mediated restoration of p16 in GBM cells induced, as expected, tumor cell cycle arrest in G1-S phase [67,68]. Surprisingly, this overexpression of p16 also caused an unexpected reduction in GBM cell invasion, resulting from decreased activity of matrix metalloprotease 2. This important anti-invasive effect is remarkable since it was not observed after restoration of the tumor suppressor p21/WAF, which prevents G1-S transition by a molecular mechanism similar to p16 [67].

The third major tumor suppressor regulating glioma growth and invasion is the Phosphatase and Tensin Homologue (PTEN), which is lost, mutated or inactivated in 40%–50% of all gliomas (~25% of primary GBMs) [58], resulting in high levels of dys-regulated PI3K activity and downstream signaling [69]. Adenoviral re-expression of PTEN in GBM cells inhibited Akt kinase activity, leading to tumor cell apoptosis [70]. Infection with this virus was also shown to decrease metalloprotease expression and glioma cell invasion *in vitro* [71]. When tested in GBM-bearing mice, adenoviral restoration of PTEN has shown important effects on the tumor microenvironment, inducing an anti-angiogenic response even in presence of pro-angiogenic stimuli such as loss of p53 or presence of constitutive EGFR activity [72].

Another important example of viral-delivered tumor suppressor strategy has been demonstrated with p27, an inhibitor of Rb phosphorylation that arrests the cell cycle in G1. p27 levels are regulated by complex feedback loops involving phosphorylation of this protein in Thr^{187} and further proteasomal degradation [73]. p27 activity was restored in GBM cell lines and GBM-derived primary cells using adenovirus to carry either wild type (Ad-p27wt) or a degradation-resistant Thr^{187}-mutant (Ad-p27mt, $\text{Thr}^{187}\text{Ala}$). In all cases, recovery of functional p27 promoted Rb dephosphorylation, apoptosis, and suppression of tumor growth [68]. Interestingly, while p27wt arrested the cell cycle in G1-S transition as expected, p27mt did so at the G2-M checkpoint by undefined mechanisms that were not observed in other cell types. Additional studies using adenoviral-restored p27 have demonstrated that this tumor suppressor reduces GBM growth *in vivo* as well as local invasion and tumor-induced neo-angiogenesis, with these effects being caused by a cytoskeletal anti-migratory effect of p27 both in GBM cells and tumor-associated endothelial cells [74].

2.3. Viral Delivery of Immunomodulatory Genes

The CNS is relatively isolated from systemic immune responses and is therefore difficult to induce the immune system to mount an effective local anti-tumor response against gliomas [42]. This difficulty is increased by the ability of glioma cells to suppress and effectively evade cellular immune responses [9]. In order to promote effective immunotherapy against glioma, viruses have been engineered for targeted delivery and expression of cytokines that activate and recruit immune effectors to the tumor.

An excellent example of this strategy was the early use of a replication-deficient adenovirus carrying the gene for the potent immune-boosting cytokine interferon beta (IFN-beta) under control of the CMV promoter [75,76]. Using this vector, IFN-beta was expressed in pre-established, subcutaneous gliomas in nude mice, resulting in enhanced immune cellular response against the tumor (lymphocyte infiltration), tumor regression, and significantly prolonged animal survival [76]. This strategy reached a phase I clinical trial for recurrent malignant glioma, where an IFN-beta-expressing, non-replicating adenoviral vector was stereotactically injected in the tumor before surgical resection [77]. The trial demonstrated that the virus inoculation was safe and well tolerated, while analysis of the resected tumors demonstrated dose-dependent induction of local inflammation and tumor necrosis.

Using recombinant parvoviruses, another immunomodulatory strategy was attempted by simultaneous delivery of IFN-gamma-inducible protein 10 (CXCL10) and TNF-alpha in a syngeneic mouse model of GBM [78]. Results showed synergistic activity of both vectors and complete regression of tumors generated from cells that had been transduced with both cytokines before implantation. Multiple mechanisms were proposed to contribute to this synergy, including CXCL10-mediated recruitment of activated T and NK lymphocytes to the tumor, inhibition of tumor angiogenesis by CXCL10, and TNF-alpha-mediated tumor necrosis and maturation of dendritic cells. Despite these exciting results, the effect of the viruses in naïve pre-established tumors was marginal, resulting in delayed tumor growth but no regression [78].

Viral-mediated delivery of other interleukins has not been as extensively exploited in GBM as in other cancers, but work in this direction has definitely shown therapeutically relevant results. Non-replicating adenoviral-associated virus (AAV) and replicating HSV have been employed to deliver IL-12 in experimental models of GBM [79–81], resulting in local immune mechanisms such as increased IFN-gamma expression, microglial activation, and recruitment of T and NK lymphocytes, with a significant antitumor effect.

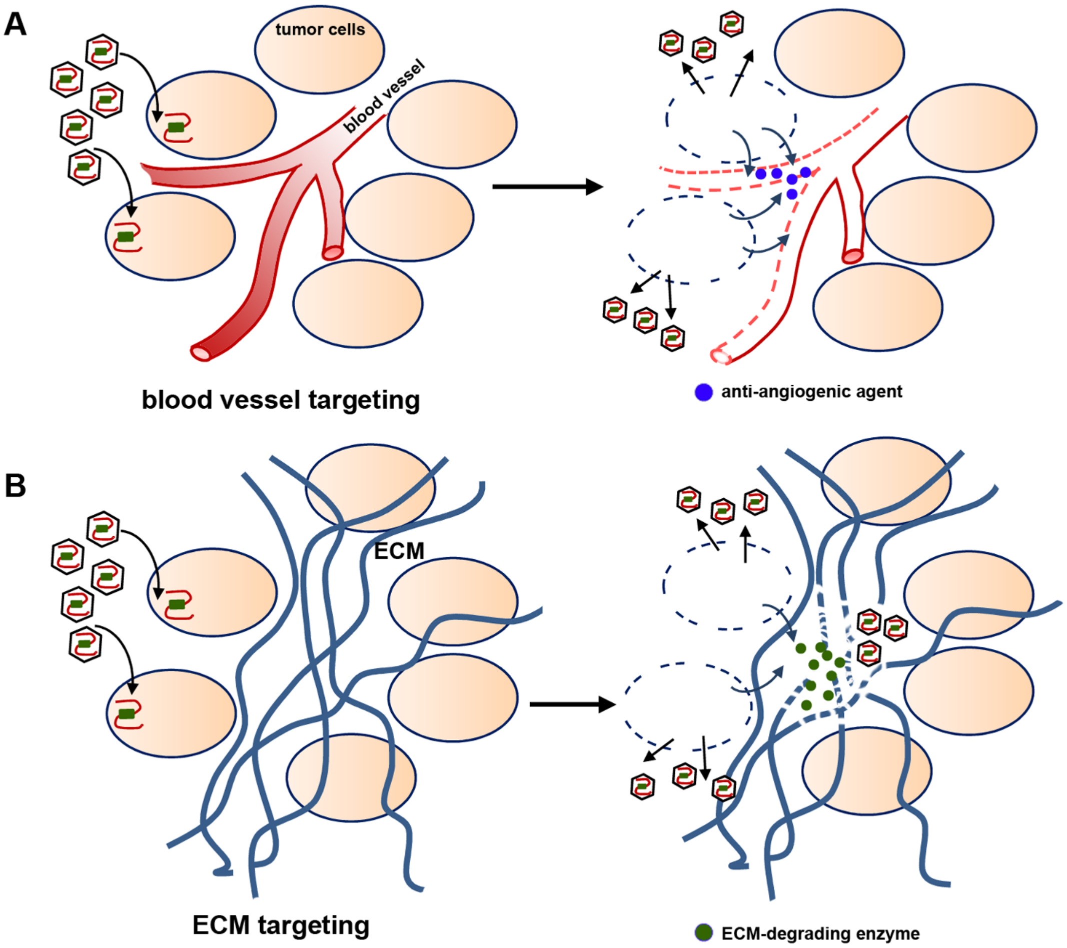
2.4. Viral Delivery of Genes That Modify the Tumor Stroma

The gene-delivery strategies described in the previous sections (as well as viral-mediated oncolysis, in the following section) target specifically the tumor cells for immediate cell death. Additional effects such as reduced tumor vascularization and invasion may be observed (and welcomed) but are not usually part of the design rationale. However, viruses can also be engineered to deliver genes that specifically affect the tumor microenvironment. Two clear examples of this strategy are viruses carrying anti-angiogenic genes or genes that remodel the tumor extracellular matrix (as illustrated in Figure 2).

Initial attempts to specifically inhibit glioma angiogenesis with gene therapy involved the intratumoral injection of retrovirus and AAV carrying the antiangiogenic factor angiostatin [82,83]. A subsequent study, using systemic instead of local delivery, followed a similar approach with adenoviral-delivered endostatin [84]. In all cases tumor vascularization was significantly inhibited and tumor growth was reduced more effectively than with the parental viruses. A more recent approach has combined anti-angiogenesis with viral oncolysis using conditionally-replicating oncolytic HSV (see details of this virus in the following section). Two oncolytic HSVs were engineered to express the anti-angiogenic protein vasculostatin under control of the promoter for the early viral gene IE4/5 [85,86]. Secretion of vasculostatin was detected a few hours after infection of glioma cells and results *in vivo* with both viruses showed remarkable reduction in microvessel density, tumor perfusion, and overall tumor progression. Coupled with their oncolytic ability, these antiangiogenic viruses offered significantly better antitumor efficacy when compared with their parental HSV strain.

Delivery of genes that can remodel the tumor extracellular matrix (ECM) has been rarely attempted, despite the fact that this matrix is the most immediate physical barrier to viral dispersion and a significant factor that limits viral effects to short distances from the inoculation site [87]. Indeed, pre-injection of proteases that can degrade tumor ECM proteins enhances subsequent viral spread and infection [88]. Following this rationale, a conditionally-replicating oncolytic HSV was engineered to express the bacterial enzyme chondroitinase ABC-I, which degrades major components of the glioma ECM such as hyaluronan and chondroitin sulfate proteoglycans [89]. The resulting virus demonstrated increased efficacy against the tumor compared to parental HSV and, as expected, dispersed farther away from the sites of inoculation. Local degradation of ECM was also demonstrated, which, importantly, did not enhance the invasive ability of the remaining tumor cells.

Figure 2. Strategies targeting the GBM microenvironment. To enhance viral oncolysis conditionally-replicating oncolytic viruses may also carry genes that modify the tumor microenvironment. (**A**) Anti-angiogenic strategies: viruses carry anti-angiogenic factors that reduce vascular support of the spared tumor not reached by oncolysis; (**B**) Anti-ECM strategies: viruses carry enzymes that degrade ECM components, increasing dispersion of viral particles and oncolytic efficacy.



2.5. Replication-Competent Oncolytic Viruses

Oncolytic virotherapy (OV) can be considered a gene therapy approach where the whole virus becomes the genetic payload. OV utilizes replication-competent viruses that can infect and lyse tumor cells, with or without concomitant gene transfer [9,90,91]. OV strategies exploit two major properties of the viruses used as vehicles/lytic agents: Tropism towards cells of neural lineage/brain tumor cells, and the ability to specifically replicate in tumor cells with altered signaling pathways while sparing normal cells [90,92–94]. Oncolytic HSV, conditionally-replicating adenovirus (CRAd), reovirus, poliovirus, engineered retroviruses, Newcastle Disease virus and measles virus have been evaluated for OV therapy of GBM [95].

HSV is an enveloped DNA virus with wide tropism that replicates in dividing and non-dividing cells [9,91]. This virus establishes latent infection in post-mitotic neurons and is especially suitable for therapeutic strategies in the CNS. To reduce neurovirulence, engineered versions have been attenuated through deletions in genes necessary for viral replication in normal cells, such as the ribonucleotide reductase ICP6 (*UL39*) and the protein synthesis promoting factor ICP34.5 (*γ34.5*) [96]. Two recombinant oncolytic HSV have reached clinical trials for recurrent high-grade glioma: The virus HSV G207 (with an inactivating insertion in ICP6 and deletions in both copies of γ34.5) was tested in a phase I clinical trial where no dose-limiting toxicity was observed up to the maximum tested dose of 3×10^9 p.f.u. The study reported eight patients (out of 21) with radiographic/histologic response to the treatment and two long-term survivors [97]. A further phase Ib trial demonstrated the safety of multiple dose delivery of the same virus, including inoculation both in the pre-resected tumor and the post-resection cavity [98]. A similar virus, HSV1716 (deleted in both copies of γ34.5) reached phase II trial for intratumoral delivery. HSV1716 treatment showed positive response in three out of twelve patients and did not cause toxicity even when patients developed antibodies against the virus [99,100]. A disadvantage of these models is the required deletion of viral genes (γ34.5), which attenuates viral replication and limits the virus efficacy [101]. A new generation of oncolytic HSVs is therefore being studied in pre-clinical models and prepared for clinical trials. A major modification that enhances the efficacy of these viruses is the conditional re-expression of viral genes under promoters that are overexpressed in brain tumor cells compared to normal cells, such as Nestin, GFAP, or survivin [102–104].

CRAds with deleted viral genes have been employed as alternative to oncolytic HSV. Adenoviruses are non-enveloped DNA viruses that infect proliferating and quiescent cells and can integrate, with low frequency, into a defined region of the host genome [9,91]. Two extensively studied CRAds in glioma are ONYX-015 and Ad5Delta24, both of which target cells with dys-regulated signaling pathways. ONYX-015 has a deletion in the gene coding for the viral protein E1B that binds and inactivates p53. Due to this deficiency, the virus was originally expected to replicate selectively in p53-deficient cells (*i.e.*, tumor cells) [105], although it was later shown that its oncolytic activity in gliomas was independent of p53 status and even increased in wild-type p53 glioma xenografts [106]. ONYX-015 was tested in a phase I trial for recurrent malignant gliomas, being injected only in the post-resection cavity [107]. Although the study could not demonstrate a significant antitumor efficacy, it showed absence of serious adverse effects and good tolerance to the virus, without reaching maximum tolerable dose even at 10^{10} p.f.u.

Similarly to ONYX-015, Ad5Delta24 has a genetic deletion for the viral protein E1A, which inactivates the Rb tumor suppressor. Ad5Delta24 therefore replicates in glioma cells with a deficient Rb pathway, causing significant growth inhibition of xenografted tumors in mice [108]. This virus was further engineered by introducing the integrin-binding RGD motif in the knob domain of the viral fiber protein (Ad5Delta24-RGD) [109], which enhanced the specific targeting of tumor cells and increased oncolytic efficacy against gliomas [110]. Ad5Delta24-RGD is currently being tested in a phase I clinical trial for recurrent malignant glioma (NIH trial NCT00805376, Table 1) [111].

A novel CRAd that has been recently developed replaces the strategy of viral gene deletion by using instead the promoter of a gene highly expressed in glioma cells (survivin) to drive the expression of E1A [112]. This virus (CRAd-survivin-pK7) has in addition a poly-lysine sequence added to the fiber knob, which enhances the binding to cell surface proteoglycans and increases viral entry and anti-tumoral efficacy against differentiated as well as stem-like glioma cells [112,113].

In addition to the extensively used HSV and CRAds, other viruses have been engineered for OV of glioma, including measles, vaccinia, rhabdoviruses and polioviruses [114,115]. Of these, the measles paramyxovirus (MV, attenuated Edmonston strain) was the earliest to be considered as a potential oncolytic agent since initial reports in the 1970s suggested that measles infection was associated with regression of lymphoma and leukemia [116,117]. MV targets cells that express the membrane receptors CD46 and Signaling Lymphocyte Activating Molecule (SLAM), inducing the formation of multinucleated syncytia followed by apoptosis. MV variants have been engineered to express IL-13 [118] or a single-chain antibody against the vIII deletion variant of EGFR [119], therefore re-targeting the viruses against proteins highly expressed on the surface of glioma cells and increasing their oncolytic efficacy. Additional engineering of MV to express the circulating carcinogenic embryonic antigen (MV-CEA) has been used to monitor the course and maintenance of MV infection [120]. Toxicological data in macaques has shown absence of neurotoxicity of MV-CEA [121] and supported an ongoing phase I clinical trial (NIH trial NCT00390299, Table 1). Recent data has also shown that MV is highly effective against glioma-derived stem-like cells [122], which makes it an attractive approach against this highly resistant population of tumor cells.

2.6. Advantages and Challenges of Viral-Based Gene Therapy

Having evolved for horizontal gene transfer, viruses are the most efficient carrier system to deliver genes to tumor cells. Additional modifications described in this review, such as re-targeting and conditional replication have considerably improved the specificity and efficacy of viral vectors, many of which have reached clinical trials for GBM. Moreover, compared to other particle-like carriers (see Sections 4.1–4.3 on nanotechnology), viruses induce robust bystander cytotoxic effect, attract cellular immune response towards the infected cells, and can directly kill infected glioma cells by cell lysis. These features absent in other vehicles for gene delivery have made viruses one of the most valuable tools for gene therapy of GBM.

On the other hand, viral carriers and oncolytic viruses still face considerable challenges for successful long-term therapeutic effects. A major difficulty is the limited spread and persistence of the virus in the tumor tissue, caused by factors such as low efficiency of initial infection, rapid clearance of the viral particles by innate immune cells, and physical barriers that limit particle dispersion [123]. Some of these challenges are being actively addressed through strategies involving viral engineering and combination with other antitumor agents. Major developments in the field include improved re-targeting towards GBM-specific receptors [124], combination with drugs that reduce the immune response to the virus [125], "cloaking" of the virus inside carrier cells (described in the following section), enhanced infusion of viral particles via convection-enhanced delivery, and engineering of viruses to express genes that facilitate their physical dispersion [89], among others. As current limitations are overcome, viral-based approaches (alone or combined with conventional therapy) will remain a major choice for gene therapy of GBM.

3. Stem Cell-Based Gene Therapy of GBM

Together with viruses, cells have been used to deliver genetic material to brain tumors for the past twenty years. Indeed, retroviruses themselves were the first genetic payload delivered by cells injected into the tumor stroma [18,19]. Examples of successful carriers have included fibroblasts and HEK293 cells, both used to deliver replicating viruses, suicide genes (HSV-TK), and anti-angiogenic factors in gliomas [126,127]. A major limitation of these cell types has been their lack of migratory ability inside the tumor, a deficiency that was considered a major cause of therapeutic failure in clinical trials of viruses and suicide genes delivered by cells [37]. Currently, the most widely employed cellular carriers are stem cells (SCs) of neural, mesenchymal or embryonic origin. While SCs have been studied for only half as long as viral carriers and only recently reached the clinical stage, they have proved one of the most attractive vehicles to combine gene therapy with virotherapy and conventional therapies. The importance of SCs is underscored by a fundamental property absent in other delivery vehicles: their ability to migrate towards the tumor cells even when injected peripherally [128,129]. This critical feature allows them, in principle, to reach the disseminated tumor cells that are characteristic of GBM [128]. As expected, SCs have already been extensively tested as vehicles for most of the approaches described in the previous sections: delivery of suicide genes, oncolytic viral particles, anti-angiogenic factors, and immune-boosting cytokines, among others.

3.1. Neural Stem Cells

Neural Stem Cells (NSCs) are multipotent progenitors of the neural lineage with indefinite self-renewal and ability to differentiate into neurons or glial cells [130]. They are not only highly adapted to the neural environment and architecture [131] but also share many properties (such as cell motility mechanisms [119]) with the elusive glioma stem-like cells. Engineered NSCs were first used against gliomas in 2000 to deliver the cytokine IL-4, therefore improving the immune response against the tumor [132]. Subsequently, they have been largely employed in two major approaches for antitumor gene therapy: as infected carriers of oncolytic viruses or as engineered cells expressing therapeutic genes.

Using NSCs as carriers of oncolytic viruses -which lyse the carrier cell and infect glioma cells- has become an interesting approach with multiple possible advantages over the inoculation of viral particles: migratory NSCs may deliver the viruses at further distances within the tumor compared to virus alone; they can protect the viruses from the host immunosurveillance; and their own lysis removes them from the host after therapy [133]. Following this rationale, Herrlinger and colleagues were the first to show the feasibility of using NSCs to carry conditionally-replicating HSV into pre-implanted cerebral gliomas [134]. Similar studies were further pursued with CRAds [135,136], demonstrating that pre-loading the virus inside NSCs highly enhanced the reach of the virus within the tumor as well as its oncolytic efficacy.

Engineering NSCs to deliver transgenes rather than viruses into the tumor mass has been a more common approach, employed with suicide genes and cytokines. Both CDA and HSV-TK (described in Section 2.1) have been tested in NSC therapy of GBM (e.g., [128,137,138]) and in all cases the use of NSCs has compared favorably against non-migratory cell carriers. NSCs have also been used to carry CDA and IFN-beta cDNAs together, boosting the bystander cytotoxicity with immune response against the tumor and resulting in better antitumor response compared to CDA alone [139]. CDA-carrying NSCs are currently being tested in the first clinical study of feasibility against recurrent high-grade gliomas (NIH trial NCT01172964, Table 1).

A second group of widely tested transgenes have been immune-boosting interleukins such as IL-4, IL-12 and IL-23 [132,140,141]. These studies led to two important conclusions: First, NSC-mediated sustained delivery of interleukins was found more efficient than viral-based delivery *in vivo* [132] and resulted in improved animal survival. Second, the strong cellular immune response against the tumor (at least in the case of IL-23) resulted in long-term surviving animals resistant to tumor re-challenge, suggesting the possibility of using SC approaches to trigger long-standing antitumor immunity.

One important cytokine that has been delivered by NSCs in gliomas is the Tumor Necrosis Factor-Related Apoptosis-Inducing Ligand (TRAIL), which is capable of inducing apoptosis in tumor cells with little effect on normal cells. This effect is potentiated in S-TRAIL, a secreted chimeric protein combining the extracellular domains of TRAIL and Flt3L (a ligand for Flt3 tyrosine kinase receptor) [142]. NSCs carrying S-TRAIL were shown to migrate actively towards glioma cells, causing bystander cytotoxicity in the tumor and significantly reducing the burden of pre-implanted gliomas [143]. Moreover, combination of NSCs-S-TRAIL with adjuvant chemotherapy showed strong potentiation of the antitumor effects of temozolomide, PI-103 (a PI3K/mTOR inhibitor), and bortezomib (a proteasome inhibitor) [144–146].

A third major group of genes delivered by NSCs in glioma models includes anti-angiogenic factors such as endostatin [147], thrombospondin-1 [148], and the angiostatic factor PEX [149]. Although these factors can impair the migration of normal and tumor cells, all the studies reported that active migration of the engineered NSCs towards tumor cells was unaffected. NSCs distributed extensively in the tumor stroma, without concomitant proliferation or differentiation, and caused significant reduction of tumor growth and microvascular density.

3.2. Mesenchymal Stem Cells

Mesenchymal stem cells (MSCs) are non-hematopoietic, adult multipotent stem cells that can be isolated from multiple sources (such as bone marrow, adipose and muscle tissue, or peripheral blood), and expanded with relative ease *in vitro* [150]. These cells migrate to sites of injury and inflammation and are involved in tissue repair. Since tumors behave as non-healing, expanding wounds, they strongly attract MSCs [151]. Based on this strong homing ability, MSCs have been employed in multiple strategies against tumors, including gliomas [152].

As with NSCs, initial studies of MSCs against experimental gliomas involved the overexpression of a therapeutic cytokine (IL-2), resulting in augmented antitumor effect (compared to MSCs alone) and prolongation of animal survival [153]. Due to their easy availability for autologous transplantation, MSCs have become a very attractive alternative to NSCs towards clinical studies, and have already been tested to deliver cytokines, suicide genes, antibody chains and viral particles to gliomas.

Suicide genes originally tested in NSCs have been evaluated in MSCs as well, including HSV-TK [144], CDA [154], and HSV-TK together with connexin-43 to enhance bystander cytotoxicity [145]. MSCs have also been used as vehicle for the suicide gene carboxylesterase [155]. A combination of MSC-delivered carboxylesterase with the prodrug CPT-11 (Irinotecan) was tested in experimental brainstem gliomas and showed effective conversion of the prodrug but only modest improvement in animal survival.

In addition to MSC-delivered IL-2, more recent animal studies have used transduced MSCs to deliver IL-7 [156], IL-12 [157], or IL-18 [158] in glioma xenografts. Strong cellular immune response was observed following infiltration of the MSCs in the tumor stroma, and resistance of the surviving animals to tumor re-challenge was observed in the studies using IL-12 and IL-18. MSCs have also been used to deliver TRAIL constructs, including a shortened form of secretable TRAIL [159] as well as the recombinant TRAIL-Flt3L fusion (S-TRAIL) [160]. Newer studies have combined MSC-delivered TRAIL with radiotherapy [161] and with the anti-inflammatory compound MK886 [162], demonstrating in both cases synergism compared to MSC-TRAIL alone.

Finally, the use of MSCs as carriers of conditionally-replicating oncolytic viruses such as CRAds has shown that MSCs are capable of suppressing the humoral immune response against the virus, resulting in increased persistence of the viral particles [163]. However, MSCs were found less efficient than NSCs to deliver the same CRAd in orthotopic xenografts and had lesser impact on animal survival [164]. Nevertheless, considerable interest remains in the use of MSCs to deliver those oncolytic viruses that have reached clinical trials, such as Ad5Delta24-RGD described in Section 2.5. MSCs carrying Ad5Delta24-RGD and injected in the peripheral circulation have been shown to reach intracranial gliomas and inhibit tumor growth [165]. Current trends suggest that, if clinical trials with the viruses are promising, the use of SCs to carry them into the tumor could be the next step to improve their therapeutic efficacy.

3.3. Embryonic Stem Cells

Embryonic stem cells (ESCs) are pluripotent cells that form the inner cell mass of the blastocyst during gestation and have unlimited proliferative capacity [166]. Difficulties in obtaining and culturing these cells—both technical and derived from current legislation on SCs—have made their use much more limited than NSC or MSC counterparts, with experiments largely focused on cytokine delivery to gliomas.

The first experiments with mouse ESCs involved engineering to express TRAIL, followed by differentiation into astrocytes using defined culture conditions. ESC-derived astrocytes enhanced apoptosis of co-cultured glioma cells compared to TRAIL alone [167]. Further experiments demonstrated that injection of ESC-derived astrocytes carrying TRAIL could induce severe necrosis in xenografted tumors [168], but no survival studies were pursued. Additional *in vitro* studies using ESC-derived astrocytes demonstrated that delivery of a different cytokine (IL-24) also increased apoptosis of co-cultured glioma cells and potentiated the effects of radiation and temozolomide [169].

Human ESC lines have more recently been used to derive NSCs and MSCs, which have been subsequently transduced to deliver the suicide gene HSV-TK [170,171]. The goal of these experiments was to show the successful conversion of ESCs into cells known to have strong tropism for gliomas, and in addition these studies demonstrated successful targeting of intracranial tumor burden and extension of animal survival.

3.4. Advantages and Challenges of Cell-Based Gene Therapy

The use of SCs as gene-delivery vehicles is supported by two unmatched advantages when compared to passive methods of gene delivery: (a) migratory ability that allows them to infiltrate the tumor mass, reaching poorly vascularized areas and the remote borders of the tumor; and (b) strong tropism that attracts them towards glioma cells even when injected peripherally, coupled with ability to cross the blood brain barrier. These two features of SCs, added to the possibility of performing extensive genetic engineering to convert them in carriers of multiple transgenes or whole viral vectors, make them a versatile tool that can be combined with conventional therapy and additional molecular therapy to deliver a large, complex payload inside the tumor.

However, despite their ability to infiltrate gliomas, SCs are essentially neutral and do not have an effect on the tumor unless engineered as gene-delivery vehicles. Since the transgenes are expressed in SCs immediately after transduction (in contrast to viral-carried genes, which are expressed only after infection of the target cells), a first and considerable technical challenge is to ensure that the SCs will survive for as long as it takes to impact the tumor cells, without dying first due to effects of suicide genes or oncolytic viruses [172]. Rapid and efficient delivery to the tumor is therefore a critical factor when SCs are introduced peripherally. Intravenous injection has been the most common route for peripheral introduction of SCs but its efficiency is limited, with less than 2% of the inoculated cells colonizing the tumor [173]. A recent alternative has used intranasal inoculation of NSCs, with a delivery efficiency estimated to be as high as 24% [174]. Additional challenges stem from the choice of SCs in terms of convenience, permanence in the tumor, and therapeutic efficacy. For example, while MSCs are easiest to obtain for autologous therapy, there is active discussion about their relative efficacy compared to NSCs for different gene-therapy strategies [164]. ESCs present, in addition, ethical and regulatory issues for collection and will likely be replaced by induced pluripotent SCs in the future.

A final and considerable factor that must be addressed with SCs is their safety when introduced in the highly aggressive, cytokine- and growth factor-rich environment of the tumor. To this day studies have shown that none of the different types of SCs employed in animal models suffered neoplastic transformation. However, previous studies have demonstrated that normal neural progenitor cells can contribute significantly to the heterogeneous total mass of PDGF-induced malignant gliomas [175]. Therefore, a desirable feature in future SC-based approaches would be the possibility of selectively eliminating the SCs (e.g., using an inducible suicide gene) after they have reached their therapeutic endpoint.

Overall, SC-based gene therapy of GBM offers enormous promise and, considering that SCs have become the choice carrier in other neuropathologies, is likely to become the fundamental component of future combinatorial strategies using gene delivery, molecular-targeting therapy and conventional chemoradiotherapy.

4. Nanotechnology-Based Gene Therapy of GBM

The use of nanotechnology, *i.e.*, manipulation of sub-micron-sized materials, to target genetic material into tumor cells is a relatively novel strategy that remains largely experimental. The only nanocarriers that have reached the clinical stage in glioma have been liposomes [9,176], which have long been used as carriers for small molecules in glioma and other cancers. Most nanotechnological approaches for gene therapy have focused in optimizing the DNA-carrying vehicles for effective targeting of tumor cells [177,178], testing many of the same candidate genes used with viruses and SCs. Vehicles that have been recently tested in pre-clinical models include novel formulations of cationic liposomes, nanoparticles, and dendrimers, among others.

4.1. Liposomes

Liposomes are artificial, lipid-based microvesicles usually employed to deliver drugs, peptides and proteins into cells. However, chemical engineering of the lipids also permits the formation of stable DNA-lipid associations that can be exploited to use liposomes as a gene-delivery vehicle. Following this concept, a liposomal vector was devised in the early 2000s to carry a plasmid coding for HSV-TK, which was given to patients with recurrent GBM in a phase I/II trial via intratumoral infusion [179], followed by administration of the prodrug ganciclovir during 14 days. Radiographic response was observed in most patients in this clinical trial, ranging from focal effects to 50% reduction in tumor volume, without major adverse events.

Cationic liposomes have also been used to transfer cytokine genes into glioma cells. A phase I/early phase II clinical trial demonstrated the safety and efficacy of this approach to deliver a plasmid coding for IFN-beta [180] in patients with recurrent malignant gliomas, following resection of the tumor. IFN-beta protein was found in the accumulated fluid in the post-surgical cavity in three out of five patients, for periods of up to ten days after injection. All patients showed positive radiographic response immediately after treatment, although the tumors eventually progressed. A more complex liposome was recently devised to carry both a therapeutic gene (TRAIL) and a cytotoxic drug (paclitaxel), combined with re-targeting via addition of a peptide (angiopep2) that facilitates blood brain barrier crossing. This liposome preparation effectively delivered TRAIL to glioma cells *in vitro* even when protected behind a barrier of normal epithelial cells [181]. More importantly, peripherally delivered angiopep2-liposomes reached intracranially xenografted gliomas in mice, causing local apoptosis in the tumor and extending animal survival.

Other liposomal preparations have modified not only the surface of the vesicle but also its carrier core. For example, magnetite-core cationic liposomes respond to alternating magnetic fields generating heat. This effect can be used to activate a heat-shock sensitive promoter in the DNA carried by the liposome, thus regulating expression of the therapeutic gene [182]. Using this strategy, Ito and colleagues injected paramagnetic liposomes carrying TNF-alpha under control of the heat-inducible promoter *gadd153* into subcutaneous gliomas implanted in nude mice [183]. Their results showed heat-regulated expression of TNF-alpha protein in the tumor and subsequent retardation of glioma growth.

A recent and ingenious liposomal design used air-cored liposomes, subsequently loaded with siRNA against the anti-apoptotic protein sirtuin 2 [184]. The liposomes were injected in subcutaneously-implanted gliomas in nude mice, followed by exposure to brief low-frequency ultrasound. This induced cavitation (bursting) of air bubbles in the liposomal core, damaging neighboring tumor cells and enhancing the delivery of therapeutic siRNA. The results demonstrated effective decrease in tumor volume and prolonged animal survival when compared to liposomes lacking siRNA or absence of ultrasound treatment.

4.2. Polymers

Cationic polymers are macromolecules that spontaneously bind DNA via electrostatic interactions. This unique property has been used commercially for cell transfection. They offer advantages such as small size and flexible chemistry that allows extensive modifications to improve biodistribution and tumor targeting.

A typical example of a linear polymer used to deliver plasmids or oligonucleotides is polyethylenimine (PEI). This polymer binds DNA strongly and has high transfection efficiency, forming small particles that enter the cells via endocytosis [185]. However, in absence of further modifications it has high cellular toxicity and cannot reach intracranial tumors when injected peripherally. Chemical engineering of PEI by addition of functional groups such as poly-ethileneglycol (PEG) or beta-cyclodextrin has proven sufficient to improve PEI permanence in circulation and in the tumor stroma [186]. PEI polymers modified by addition of myristic acid were able to cross the blood brain barrier, delivering a TRAIL-coding plasmid to intracranially implanted gliomas and increasing survival in tumor-bearing mice [187]. Similarly, PEGylated PEI was re-targeted towards glioma cells by chemical addition of an RGD-containing peptide [188]. This polymer (RGD-PEG-PEI) was injected intravenously and able to deliver TRAIL cDNA *in situ* in an intracranial glioma model, increasing animal survival.

In addition to the chemically simpler linear polymers, novel efforts have focused on using repeatedly branched polymers, known as *dendrimers*, for gene delivery. These molecules offer several advantages (such as high surface/volume ratio for DNA binding and well-known chemical behavior) [189] that have made them attractive synthetic nanocarriers for gene therapy. A commonly used dendrimer is a hyperbranched polymer of poly-amidoamine (PAMAM) characterized by biocompatibility, controlled biodegradation, low toxicity, and good accumulation in tumors with leaky vasculature [190]. A modified version of PAMAM was conjugated with nanoparticle carriers (see next section) and a viral Tat-peptide to facilitate cell membrane crossing [191]. This complex polymer (np-PAMAM-Tat) was used to deliver anti-EGFR shRNA to subcutaneously-implanted gliomas, inhibiting EGFR/Akt signaling and slowing tumor growth. Another modified version of PAMAM (Arg-PAMAM) has recently been used to deliver IFN-beta cDNA in intracranial glioma xenografts, causing selective tumor cell apoptosis and overall tumor shrinkage [192].

4.3. Nanoparticles

As their name indicates, these are nanometer-sized particles that, depending on their size (usually ranging from 20 to 50 nm in diameter) may spontaneously cross capillary walls and be endocytosed by cells. They have a rigid polymer core and a multi-functionalized surface that has been engineered to enhance DNA binding, particle diffusion, and cell-membrane crossing [193]. The core of the nanoparticles can also be modified with fluorochromes or metallic iron to facilitate *in vivo* imaging or to make them responsive to magnetic stimuli [194,195].

Super-paramagnetic iron oxide nanoparticles (SPIONs) have been used for delivery of therapeutic agents to the CNS while being at the same time tracked via magnetic resonance imaging [196]. In a recent study, SPIONs were covalently bound to the capsid of an RGD-targeted adenovirus (replication-deficient Ad5/3-RGD) and used to track the delivery of the virus [197]. Results demonstrated that viral infectivity of glioma cells was not affected by the SPIONs and that the virus could be tracked in a large (porcine) brain, but no studies were performed with gliomas *in vivo*.

More complex version of SPIONs have used magnetic nanoparticles simultaneously functionalized on their surface with PEG (to bypass the blood brain barrier), chitosan (to improve half-life in circulation), PEI (to adsorb the therapeutic DNA) and chlorotoxin, a re-targeting peptide against glioma cells [198,199]. These multifunctional SPIONs have been used to demonstrate proof-of-principle delivery of siRNA and marker cDNA (eGFP) to glioma cells and subcutaneously-implanted gliomas.

4.4. Advantages and Challenges of Nanocarrier-Based Gene Therapy

Being completely synthetic, nanocarriers offer strong advantages as vehicles for gene therapy of GBM: size, structure and chemical composition of the carrier can be accurately tailored to enhance biodistribution, low toxicity, and optimal cell penetrance. The size of the DNA that can be carried is not as limited as in biological carriers, does not require prior genetic engineering of the carrier, and allows in principle any combination of plasmids and oligonucleotides as desired. The surface of nanocarriers is based on well-studied polymers that are biocompatible, biodegradable, and do not induce immune responses against the vehicle, as it is common when using viral carriers. As an additional advantage, the core of the carrier can also be optimized to track it using fluorescence or magnetic resonance, a property that would require additional modifications in viral or cell-based carriers.

On the negative side, the major disadvantage of nanocarriers is that they are completely passive vehicles for gene delivery and their efficacy depends on the physical and chemical properties of the materials used to build them. Nanocarriers do not migrate actively and do not have neurotropism or even cell-specific tropism, therefore the tumor specificity must be "built from scratch" and optimized more exhaustively than with SCs or viruses. Their passivity as delivery vehicle also means that their distribution in the tumor will be much more limited than that observed with SCs and even with viral carriers, which can disperse when they lyse infected tumor cells. Finally, biological effects of novel particles and polymers (and their fragments) have not yet been analyzed in long-term studies and the overall efficacy of nanocarriers has not been exhaustively compared against other modalities for gene delivery. The future of these experimental vehicles for gene therapy of GBM will depend on these efficacy studies, using nanocarriers with improved cell type-specificity delivered via convection-enhanced delivery and combined with conventional therapies.

5. Conclusions

Gene therapy represents today one of the more flexible and robust strategies for adjuvant therapy of GBM. As detailed in this review, gene-delivery approaches can be manipulated at multiple levels including choice of delivery vehicle, chemical or genetic engineering of the carrier, and selection of molecular targets, among others. This wide range of manipulations can be extensively exploited to optimize biodistribution, persistence, specificity, and targeting effects of the therapeutic agents, arguably to a much further extension that what can be achieved with improvements in conventional chemoradiotherapy. Optimized gene therapy approaches have repeatedly reached the clinical stage: A brief query of clinical trials listed by the Journal of Gene Medicine Clinical Trial website [11] and trials registered with the US National Institutes of Health [10] reveals, at the time of this writing, over a dozen active studies to deliver genetic material in malignant gliomas (Table 1). This underscores the extent to which gene therapy has become one of the most important approaches in molecularly-targeted therapy for GBM, and indicates that future developments in this field will continue improving the therapeutic options for this devastating disease.

Acknowledgments

The authors wish to acknowledge fruitful discussions with all members of the Chiocca and Viapiano laboratories in the Department of Neurosurgery, Brigham and Women's Hospital. This work was supported by grant 5R01CA152065 to MSV.

Conflicts of Interest

The authors declare no conflict of interest. E.A.C. is involved in two listed active trials using adenoviral-delivered HSV-TK.

Simple Summary: This review article is a summary of the current state of knowledge regarding the genetics of pancreatic cancer and a presentation of possible treatment options reflecting genomic medicine advances and a personalised medicine approach. Several oncogenes in which somatic changes lead to the development of tumours, including genes BRCA1/2 and PALB2, TP53, CDKN2A, SMAD4, MLL3, TGFBR2, ARID1A and SF3B1, are involved in pancreatic cancer. Between 4% and 10% of individuals with pancreatic cancer will have a mutation in one of these genes. Six percent of patients with pancreatic cancer have NTRK pathogenic fusion. It is estimated that from 24% to as many as 44% of pancreatic cancers show homologous recombination deficiency (HRD). The most common cause of HRD are inactivating mutations in the genes regulating this DNA repair system, mainly BRCA1 and BRCA2, but also PALB2, RAD51C and several dozen others.

Abstract: The number of cases of pancreatic cancers in 2019 in Poland was 3852 (approx. 2% of all cancers). The course of the disease is very fast, and the average survival time from the diagnosis is 6 months. Only <2% of patients live for 5 years from the diagnosis, 8% live for 2 years, and almost half live for only about 3 months. A family predisposition to pancreatic cancer occurs in about 10% of cases. Several oncogenes in which somatic changes lead to the development of tumours, including genes BRCA1/2 and PALB2, TP53, CDKN2A, SMAD4, MLL3, TGFBR2, ARID1A and SF3B1, are involved in pancreatic cancer. Between 4% and 10% of individuals with pancreatic cancer will have a mutation in one of these genes. Six percent of patients with pancreatic cancer have NTRK pathogenic fusion. The pathogenesis of pancreatic cancer can in many cases be characterised by homologous recombination deficiency (HRD)—cell inability to effectively repair DNA. It is estimated that from 24% to as many as 44% of pancreatic cancers show HRD. The most common cause of HRD are inactivating mutations in the genes regulating this DNA repair system, mainly BRCA1 and BRCA2, but also PALB2, RAD51C and several dozen others.

1. Introduction

Cancer remains an escalating problem worldwide. The reflection of this disturbing trend can be also noticed in Poland and backed up by the statistical data. The number of cases of pancreatic cancers (PC) in 2019 was 3852 (approx. 2% of all cancers) [1]. In 2019, 100,324 people died from cancer in Poland, including 5068 people from pancreatic cancer [1]. The course of the disease is very fast, and the average survival time from the diagnosis is 6 months [2]. Only <2% of patients live for 5 years from the diagnosis, 8% live for 2 years, and almost half live for only about 3 months [2,3]. In the case of resectable tumours, the 5-year survival rate is approximately 20%, but only 10–20% of patients are diagnosed at such a stage of disease that tumour resection is a possible option [4]. Most cases (approx. 90%) of pancreatic cancer occur after the age of 50. The risk of pancreatic cancer increases with age, reaching its peak in the ninth percentile in both sexes (45–50/100,000 inhabitants) [5]. Cases <40 years of age are extremely rare, although globally, there is an increase in this age group—which is usually associated with worse prognosis [2]. Existing studies indicate that the progression of the disease from the initiation to the formation of metastatic pancreatic cancer takes up to 15 years [6]. This creates enough time to recognize the disease early. However, the diagnosis of pancreatic cancer at an early stage, despite recent advances in diagnostic methods, is still very difficult, resulting in the delayed implementation of a potentially effective treatment. Pancreatic cancer patient survival has only slightly improved over the past two decades [7]. At the time of diagnosis, up to 80% of patients already have advanced, metastatic disease, which precludes the effective use of surgical treatment and many other modern therapeutic methods [2].

There are two main types of pancreatic cancer: non-endocrine pancreatic cancer and neuroendocrine pancreatic cancer [8]. The non-endocrine type is divided into four subtypes. The most common of these is adenocarcinoma, which is the cause of roughly 90% of pancreatic cancer diagnoses. This type of cancer emerges in the lining of the pancreatic ducts. Rarely, it can also have its origin in the cells that produce the pancreatic enzymes. Another subtype of the non-endocrine cancer type is colloid carcinoma, which accounts for 1–3% of non-endocrine pancreatic cancers [8]. This subtype has its origin in the intraductal papillary mucinous neoplasm. Colloid carcinoma is easier to treat than other pancreatic cancer types [9].

Adenosquamous carcinoma is the next type of non-endocrine pancreatic cancer. It is the most aggressive type and accounts for 1–4% of diagnoses. The rarest type of pancreatic cancer is squamous cell carcinoma, which is also the least studied subtype, but studies suggest that it has its origins in the pancreatic ducts. The second large class of pancreatic cancers are neuroendocrine pancreatic cancers. This type is rarer than the non-endocrine class, making up less than 5% of cases. This class of cancers develops from the pancreatic gland that releases pancreatic hormones (glucagon and insulin) into the bloodstream [8,9].

On the other hand, the possibility of targeted treatment is the major motivation for the identification of genetic biomarkers in pancreatic cancers. Several genetic biomarkers have proven to be associated with a treatment outcome, among them variants in the following genes: *K-ras*, *hENT1*, *DCK*, *CDA*, *DPD*, *HMLH1*, *TP1DPD*, *HER2* and *SMAD4* [10]. Treatment options depend on the molecular profile of the tumour. For example, tumours with *NTRK* fusion may be treated with a larotrectinib; olaparib treatment targets a mutation in the *BRCA1* or *BRCA2* gene, and pembrolizumab is approved by FDA only in the cancers with MSI-H (microsatellite instability high) or MMR-D (mismatch repair deficiency).

Most of the clinical trials that involve molecular profiles of the pancreas tumour are those including patients with germline *BRCA1*/*BRCA2* pathogenic variants. Most of these involve PARPi, either as a single treatment, together with other oncostatics or as a maintenance therapy. However, in an early stage, there are promising therapies targeting other molecular pathways. For example, there are ongoing trials to implement RAS-directed therapies in pancreatic cancer treatment. One of such implementations is neoantigen T-cell receptor gene therapy, in which a single infusion of genetically engineered autologous

Pobrano z / Downloaded from Repository of Wrocaw University of Environmental and Life Sciences 2025-10-15 21:43

T-cells that target mutant KRAS G12D driver mutation resulted in the regression of metastatic pancreatic cancer [11]. Some studies including immunotherapies, e.g., PD-1 immune checkpoints, are recruiting [12,13]. Though the search for a treatment is ongoing, there are some prominent possibilities for early detection. One of these is the correlation between new-onset diabetes and pancreatic cancer [14]. In a situation in which time is of the essence, this might be a new area to expand upon in early detection. Moreover, it has been shown that patients with diabetes mellitus (DM) have significantly higher median overall survival than those without DM [15].

Meanwhile, in many other cancers, patient mortality is systematically decreasing, which is related, inter alia, to the personalization of therapies and the use of targeted drugs.

2. Genetics of Pancreatic Cancer

Pancreatic cancer, like all cancers, is a genomic disease caused by abnormalities in the sequence or structure of the genomic DNA. Genetic changes leading to neoplasm can be initiated by family predispositions (germline mutations) or by acquired changes (somatic mutations), which occur, for example, because of chronic inflammation in the pancreas [6]. Due to the inaccessible location of many tumours, difficult sampling and the extremely short survival time of patients, the exact molecular basis of the formation of these neoplasms has not been well understood. It is estimated that a family predisposition to pancreatic cancer occurs in about 10% of cases [16,17]. There are also other genetic pathologies that may indirectly lead to the development of pancreatic neoplasms, including hereditary pancreatitis, during which recurring episodes of acute inflammation occur in childhood. There are also several other oncogenes in which somatic changes lead to the development of pancreatic tumours, including genes *BRCA1*, *BRCA2*, *PALB2*, *TP53*, *CDKN2A*, *SMAD4*, *MLL3*, *TGFBR2*, *ARID1A* and *SF3B1* [18–20]. There are also gene fusions, especially in the case of *NTRK*: it is estimated as many as 6% of patients with pancreatic cancer have *NTRK* pathogenic fusion [21]. Currently, the most promising targeted therapies for pancreatic cancer target tumours that are characterised by homologous recombination deficiency (HRD). The mechanism of homologous recombination is responsible for the repair of DNA double-strand breaks [22]. This damage leads to numerous genomic rearrangements and the so-called genomic instability [23]. It is estimated that from 24% to as many as 44% of pancreatic cancers show HRD [23]. The most common cause of HRD are inactivating mutations in the genes regulating this DNA repair system, mainly *BRCA1* and *BRCA2*, but also *PALB2*, *RAD51C* and several dozen others [22].

3. Genomics of Pancreatic Cancer

The mutation's diversity can be studied thanks to recent advances in sequencing technologies (next-generation sequencing; NGS) and computational biology, which have provided the possibility of the reliable detection of molecular alterations, not only for single genes but on the whole genome scale [24]. According to Felsenstein et al., recent genomic studies, including whole exome and whole genome sequencing, have contributed to a better understanding of the complex genomic changes due to a combination of large-scaled structural variants (SV) and widespread single-nucleotide variants (SNV) [25]. As an example, SVs can affect tumour suppressors, including *SMAD4* and *CDKN2A*, by causing homozygous deletion or inactivating alterations [26]. Pancreatic ductal adenocarcinoma subtypes (stable, locally rearranged, scattered, or unstable) have been defined based on the associated SV's features, such as the SVs' count, the predominance of specific SV types and SV's distribution across the genome of each patient [19]. Moreover, *BRCA1*, *BRCA2*, *PALB2* and other genes from the Fanconi anaemia (FA) pathway altered by structural germline or somatic mutations are associated with the unstable subtype, which in turn is caused by the inability to repair double-stranded DNA breaks [27]. In addition, Zhang et al. detected recurrent somatic mutations in multiple genes, including *KRAS*, *TP53*, *CDKN2A*, *SMAD4*, *ARID1A* and *CDKN2B,* in 1080 Chinese patients with pancreatic ductal adenocarcinoma, demonstrating the genomic characteristics on a large scale [28].

Several SNVs have been found to be associated with pancreatic cancer. Some of the most common mutations are the so-called BRCA1 and BRCA2 mutations (as shown in Table 1). In Table 1, the polymorphisms in the PALB2 gene are shown, which have also been found to be associated. Similarly, the mutations in the CDKN2A, KRAS and genes that are related to PC are summarised in Table 1, as well as mutations in the GNAS, ATM, MLH1, MSH2, MSH6 and PSM2 genes (found to cause pancreatic cancer directly or indirectly). Mutations in the genes encoding the CPA1 and CPB1 carboxypeptidases have also been found to be causal (shown in Table 1).

Table 1. Mutations in genes related to pancreatic cancer.

SNP ID or SNP Location	Germline/Somatic	References
SNPs located in the BRCA1 (location: 17q21.31) and BRCA2 gene (location: 13q13.1)	germline	[29]
Mutation in the PALB2 (parner and localiser of BRCA2) gene (location: 16p12.2)	germline	[30]
The KRAS G12D, KRAS G12V and KRAS G12R mutations in the KRAS gene (location: 12p12.1)	somatic	[31]
The KRAS G12R mutation in the KRAS gene (location: 12p12.1)	somatic	[32]
Mutations in the gene (location: 11q22.3) encoding the ATM serine/threonine kinase and the gene (location: 9p21.3) encoding the CDKN2A cyclin-dependent kinase inhibitor 2A	germline	[33]
Mutation in the GNAS gene (chromosome 20)	somatic	[34]
Mutation in the ATM gene	germline	[35]
Mutations in the MLH1, MSH2, MSH6 and PSM2 genes	germline	[36]
Mutations in the genes encoding the CPB1 and CPA1 carboxypeptidases	germline	[37]

Currently, one of the biggest issues in pancreatic cancer treatment is the considerable genetic heterogeneity among pancreatic cancer types and patients. Consequently, many generalised therapies targeting only selected mutations or pathways that are present in a subset of carcinomas are often not effective. Therefore, genome-wide studies are crucial for understanding the contribution of variable genetic mutations to the carcinogenesis, progression and metastasis of pancreatic cancer in order to offer a personalised medicine approach by providing implications for further clinical achievements and drug development [21,38]. Unfortunately, the molecular characterisation in pancreatic cancer is not yet standard in clinical care, but great efforts are being made to use multiple insights provided by recent NGS-based studies in clinical trials [39]. According to Felsenstein et al., genetic alterations may be used to develop diagnostic markers for early detection, disease progression and novel targeted therapies [25]. As an example, modern screening methods, such as the analysis of pancreatic cysts and duodenal fluid, as well as circulating tumour DNA (ctDNA), incorporate the detection of molecular alterations. Mutations in KRAS or GNAS, which are present in more than 96% of patients with a mucin-producing

Pobrano z / Downloaded from Repository of Wrocaw University of Environmental and Life Sciences 2025-10-15 21:43

premalignant neoplastic cyst, can distinguish harmful precursor lesions from benign cysts (e.g., serous cystadenomas) [40,41]. Moreover, altered late driver genes such as TP53 and SMAD4 are even more accurate markers that differentiate cysts requiring urgent clinical intervention from those that can be safely monitored. Mutations in TP53 and SMAD4 are common events in duodenal fluids from patients with pancreatic ductal adenocarcinoma and may be used to differentiate them from control patients. This is possible thanks to the innovative digital NGS technique detecting even low-abundance mutations down to 0.1–1% mutation prevalence. According to Yu et al. [42], mutations of TP53 and SMAD4 genes are often detected in duodenal fluids from patients with pancreatic ductal adenocarcinoma. Interestingly, these mutations allow for distinguishing patients with pancreatic ductal adenocarcinoma from control patients with non-suspicious pancreata. The "liquid biopsy" relying on ctDNA sequencing collected from peripheral blood samples is a powerful technique in metastatic pancreatic cancer recognition that can be used to identify invasive cancers earlier and to monitor patients with recognized cancer. It may be especially useful in the prediction of cancer recurrence, even before a computed tomography scan, and is correlated with survival among metastatic and resected patients [43,44].

It cannot be denied that in the last years, the oncological approach has also been revolutionised by a growing personalisation of the treatment. According to Melisi et al., this precision oncology approach is possible thanks to NGS, which enables genomic profiling [45]. The authors identified genomic alterations in 68 pancreaticoduodenal cancer patients who failed standard treatments. The mutations were characterised based on the ESMO Scale of Clinical Actionability for molecular Targets (ESCAT), which classifies cancer patients who are likely to respond to precision medicines. According to ESCAT, at least one alteration ranking of tier I, II, III or IV was detected in 8, 1, 9 and 12 patients, respectively (44.1%). The most frequent alterations with clinical evidence of actionability (ESCAT tier I-III) affect genes of the RAF (10.3%), BRCA (5.9%) or FGFR pathways (5.9%). The results obtained in this study enabled the selection of patients receiving a molecularly targeted matched therapy. Inconveniently, this genomic profiling method may be used only when standard treatments fail and in young patients with a good performance status [39,45].

The significance of genomic studies is not to be overestimated, and the full characteristics of the pancreatic genome may have promising implications for further clinical significance and drug development. Therefore, not only do known genes need to be studied, but also novel mutated coding regions, as well as non-protein coding genomics locations, such as non-coding RNA [46] and regulatory regions [47], that are likely to have functional significance in carcinogenesis. Such mutations located in functionally important genomic structures may represent putative predictive markers at the early stage of disease, before the onset of symptoms has an essential role in treatment and survival rates.

4. Risk of Metastasis and Genetic Background of the Process

Pancreatic cancer is an aggressive tumour with frequently occurring distant metastases that can appear in virtually every organ. The liver is usually the most affected, followed by the lungs, peritoneum and bones. Various factors are associated with a metastatic pancreas tumour in comparison to an early-stage pancreas tumour, among them non-coding RNAs, transcription factors, growth factors and oxygen conditions as well as mutations [24,48]).

Several studies have aimed to characterise genomic instability in metastatic pancreatic cancer. Campbell et al. reported that an instability pattern in pancreatic metastatic cancer is different, e.g., from that in metastatic breast cancer [49]. The pancreatic cancer could be characterised by breakage–fusion–bridge cycles that predicate specific abnormalities of cell-cycle control, namely, dysregulation of the G1-to-S transition and an intact G2–M checkpoint [49].

Moreover, selected genes play a role in the increase in pancreatic cancer metastatic activity. For example, a *DPC4* expression metastatic pancreatic cancer was higher

Pobrano z / Downloaded from Repository of Wrocaw University of Environmental and Life Sciences 2025-10-15 21:43

compared with early-stage cancers or pancreatic intraepithelial neoplasia. Loss of the DPC4 protein has been shown to correlate with a shortened survival in patients with resectable pancreatic cancers. Among matched primary and metastatic cancer tissues, the loss of MKK4 in immunolabeling was observed in 11% of primary cancers, but in as many as 37% of distant metastases, indicating that MKK4 loss correlates with metastasis formation. On the other hand, other proteins' expression, such as p53, showed no correlation between metastases and the primary tumour in immunostaining.

The differential gene expression in pancreatic cancer has been assessed with different methods, with the global genetic expression being most often assessed with an array expression. However, most of the studies compared a differential genetic expression between tumour and normal tissues, not assessing the genetic and molecular differences between early and metastatic pancreatic tumours [50]. One of the few studies comparing early cancer and metastases concluded that metastatic spread is not accompanied by reproducible changes in gene expression [51]. The studies on mice reported that 25 significant up- and 181 downregulated genes were differentially expressed when comparing the liver metastases with the primary tumour. That shows that on the expression level, some differences between primary and metastatic tumours can be delineated. Eight genes (*PAI-1*, *BNIP3l*, *VEGF*, *NSE*, *RGS4*, *HSP27*, *GADD45A*, *PTPN14*) were additionally validated in a semi-quantitative immunohistochemical analysis and revealed a positive correlation to the array data [52]. Further studies are needed, although they are difficult to perform, as pancreatic tumours are usually already advanced at the time of diagnosis.

Until now, a definite "metastatic cancer signature" could not be identified, although there are events that are generally associated with the metastatic potential of tumours. [49,53]. Interestingly, in pancreatic metastasis, the clonal diversity differs between metastatic sites, with metastases in the lung and liver being monoclonal and those in the peritoneum and diaphragm being polyclonal. These findings indicate that clonal diversity depends on the metastatic site [54] and suggest the role of other mechanisms, such as the microenvironment, in the malignity of pancreatic cancers [53].

5. Hereditary Pancreatic Cancer

Approximately 10–15% of all pancreatic cancers, both exocrine and neuroendocrine, are inherited. Between 10–20% of all mutations and related genetic syndromes, described in the next paragraph, can increase the possibility of developing pancreatic cancer.

Exocrine pancreatic cancer develops from exocrine cells that make digestive enzymes and secrete them into the small intestine. Between 90–95% of all pancreatic cancers are exocrine. Neuroendocrine pancreatic cancer arises from clusters of cells in the pancreas, called islets, that produce hormones. They are neoplasms that exhibit neuroendocrine phenotypes, such as the production of certain neuropeptides, large dense-core secretory vesicles and a lack of neural structures [55]. Hereditary pancreatic cancer can be divided into two categories: FPC (familial pancreatic cancer) and syndromes that do not meet the criteria to be classified as an FPC but contain mutations that may increase the risk of pancreatic cancer. FPC is a ductal adenocarcinoma pancreatic cancer that occurs in families. Patients can be identified with FPC when one or more first-degree relatives have ductal adenocarcinoma. If one first-degree family member is diagnosed with pancreatic cancer, the risk for other family-members is 4–6%. If two family members are diagnosed, the risk increases to 8–12%, and with over two positive family members, the risk is 17–32% [56].

The association of familial pancreatic cancer with other malignant neoplasms was also investigated using the "Swedish Family-Cancer Database", which includes over 11.5 million individuals. The results of this study demonstrated an association between pancreatic cancer in parents and melanoma in offspring. An increased risk of cancers of the lung, breast, small intestine, colon, testes and cervix has also been observed in people with a family history of pancreatic cancer [57].

6. Pancreatic Cancer Associated with Cancer Syndrome

Most of the scientific reports indicate an association between the appearance of specific variants, genes or environmental factors as risk factors for pancreatic cancer. However, few of them show pancreatic cancer as a risk factor for other types of cancer.

In their study, Cote and al. assessed whether a family history of pancreas cancer is a risk factor for first-degree relatives for ten specific cancers, i.e., breast, colon, bladder, lungs, lymphoma, melanoma, ovary, pancreas, prostate head, and neck. A doubled risk of lymphoma and ovarian cancer was observed in first-degree relatives of individuals with pancreatic cancer [58].

Pancreatic cancer appears to be a genetically heterogeneous disease that is an integral alteration of many cancer syndromes. Several cancer syndromes predispose one to an increased risk of pancreatic cancer. These include hereditary pancreatitis (HP), hereditary non polyposis colorectal cancer (HNPCC) or Lynch syndrome (LS), hereditary breast and ovarian cancer (HBOC), familial atypical multiple mole melanoma syndrome (FAMMM), Peutz–Jeghers syndrome (PJS), Ataxia–telangiectasia (AT), familial adenomatous polyposis (FAP), familial pancreatic cancer, familiar breast cancer, von Hippel–Lindau syndrome (VHL), Li–Fraumeni syndrome (LFS) and Fanconi anaemia [59–69]. An additional group represents cancer syndromes associated with pancreatic neuroendocrine tumours (pNETs). Approximately 1% to 2 % of pancreatic neuroendocrine tumours are present in the context of hereditary disorders [70]. These include Multiple Endocrine Neoplasia type 1 (MEN1) (Wermer syndrome), von Hippel–Lindau disease, neurofibromatosis 1 (NF-1) and the tuberous sclerosis complex (TSC) [71]. Based on this, several potential candidate genes for PC have been proposed. In a study by Hu et al., a significant association was observed between pancreatic cancer and inherited germinal mutations in the *CDKN2A*, *TP53*, *MLH1*, *BRCA2*, *ATM* and *BRCA1* genes [72]. Further studies have identified other deleterious mutations in pancreatic cancer patients in genes *CHEK2*, *MUTYH/MYH*, *BARD1*, *MSH2*, *NBN*, *PALB2* and *PMS2* [73]. The best-known syndromes associated with PC are hereditary breast and ovarian cancer syndrome and familial atypical nevus and melanoma syndrome [73]. Mutations in the *BRCA1*, *BRCA2* and *CDKN2A* genes were found in 7.4% of PC patients [74]. The risk of PC in cancer syndromes is summarised in Table 2.

Table 2. Risk of development of pancreatic cancer.

Cancer Syndrome	Gene(s)	Location	Mode of Inheritance	Relative Risk for PC Compared with the General Population	Cumulative Risk of PC (%)	References
HBOC	*BRCA2*	13q13.1	AD	3.5–10 fold	3–5% by age 70 2–7% lifetime risk	[60,75,76]
	BRCA1	17q21.31	AD	2.26–3 fold	1–3% lifetime risk	[75–77]
	PALB2	16p12.2	AD	2.37 fold	2–3% up to 80 years	[62]
PJS	*STK11/LKB1*	19p13.3	AD	76–132 fold	11–36% to age 65–70	[61,78,79]
FAMMM	*CDKN2A*	9p21.3	AD	13–38 fold	17% by age 70 up to 20% by the age of 75	[63,80,81]
VHL	*VHL*	16p13	AD	-	5–17%	[64,82]
LFS	*TP53*	17p13	AD	6–7.3 fold	-	[65,83]
FA	Fanconi anaemia complex genes: *FANCN (PALB2)* *FANNG* *FANCM* *FANCL* *FANCD1(BRCA2)* *FANCC*	16p12.2 9p13.3 14q21.2 2p16.1 13q13.1 9q22.32	AR	-	-	[66,84]

HP	*PRSS1* *SPINK1*	7q35 5q32	AD	35–70 fold	7.2–18% lifetime risk	[67,85]
FAP	*APC*	5q21	AD	4.46 fold	2% lifetime risk	[69,86,87]
LS (HNPCC)	*MLH1,* *MSH2,* *MSH6,* *PMS2,* *EPCAM*	3p22.2 2p21 2p16.3 7p22.1 2p21	AD	5–8.6 fold	1.1% up to age 50 3.9% up to age 70 6.2% up to age 75	[68,88,89]
AT	*ATM*	11q22.3	AR	5.7–6.5 fold	0.08% by age 30 6.3% by age 70 9.5% by age 80	[71]
MEN1	*MEN1*	11q13	AD	-	Frequency PET: 80–100% (microscopic) 20–80% (clinical)	[71]
NF-1	*NF-1*	17q11.2	AD	-	Frequency PET: Uncommon (0–10%)	[71]
TSC	*TSC1* *TSC2*	9q34 16p13	AD	-	Frequency PET: Uncommon	[71]

AD—autosomal dominant; *APC*—adenomatous polyposis coli gene; AR—autosomal recessive; AT—ataxia–telangiectasia; *ATM*—ataxia–telangiectasia mutated gene, *BRCA1*—breast cancer 2 gene; *BRCA2*—breast cancer 2 gene; *CDKN2A*—cyclin-dependent kinase inhibitor 2 A gene; *EPCAM*—epithelial cell adhesion molecule gene; FA—Fanconi anemia, FAMMM—familial atypical multiple mole melanoma syndrome; FAP—familial adenomatous polyposis; HBOC—hereditary breast and ovarian cancer; HNPCC—hereditary non-polyposis colorectal cancer; HP—hereditary pancreatitis; LFS—Li–Fraumeni syndrome; LS—Lynch syndrome; MEN1—multiple endocrine neoplasia type 1; *MLH1*—MutL homolog 1 gene; *MSH2*—MutS protein homolog 2 gene; *MSH6*—MutS homolog 6 gene; NF-1—neurofibromatosis1 (von Recklinghausen's disease); *PALB2*—partner and localiser of BRCA2 gene; PC—pancreatic cancer; PET—pancreatic endocrine tumour; PJS—Peutz–Jeghers syndrome; *PMS2*—PMS1 homolog 2, mismatch repair system component 2 gene; *PRSS1*—protease, Ser1 gene; *SPINK1*—serine peptidase inhibitor Kazal type 1 gene; *STK11*—serine/threonine kinase 11 gene; *TP53*—tumour protein 53 gene; TSC—tuberous sclerosis complex; *TSC1*—tuberous sclerosis complex 1 gene; *TSC2*—tuberous sclerosis complex 2 gene; VHL—von Hippel–Lindau syndrome; (-)—no data available.

6.1. Hereditary Breast and Ovarian Cancer

Hereditary breast and ovarian cancer is inherited as an autosomal dominant disorder characterised by increased risk of breast cancer, ovarian cancer and other cancers such as prostate cancer, melanoma and pancreatic cancer. The disease is associated with pathogenic or likely pathogenic variants in one of the two genes *BRCA1* or *BRCA2*. Their protein products are involved in DNA repair, recombination, transcription and tumour suppression [90]. Previous studies reported an increased risk of PC in both *BRCA1* (1–3%) [77,91] and *BRCA2* (2–7%) carriers [92,93] (Table 2). In particular, the risk appears to be evident in families of Ashkenazi Jewish descent, where *BRCA1/2* founder mutations were identified in 5.5% of Ashkenazi patients with PC [94]. Interestingly, in most studies, the risk of MS in BRCA2 carriers was higher than in *BRCA1* carriers [75]. Recent studies have also revealed genes other than BRC1/2 that have been identified as a causative factor in HBOC syndrome. These are mainly genes associated with an increased risk of breast and ovarian cancer, but certain genes also have a proven link to pancreatic cancer. These include the genes *PALB2, TP53*, *STK11, ATM, MLH1* and *MSH2*. Interestingly, they are also strongly associated with other cancer syndromes [95].

6.2. Familial Atypical Mole and Multiple Melanoma Syndrome

Familial atypical multiple mole melanoma syndrome is an autosomal dominant inherited disorder characterised by multiple dysplastic nevi and melanoma [96]. Approximately 20–40% of patients with FAMMM have a germinal mutation in the *CDKN2A* gene, located on chromosome 9p21, but only about 1% have a mutation in another *CDK4* gene on chromosome 12q14 [97,98]. Some *CDKN2A* mutations have also been linked to

Pobrano z / Downloaded from Repository of Wrocaw University of Environmental and Life Sciences 2025-10-15 21:43

malignancies other than FAMMM, particularly PC [97]. The association between FAMMM syndrome and PC is well documented. *CDNK2* mutations are associated with an increased pancreatic cancer incidence of up to 20% by age 75 [99]. The risk of PC in patients with FAMMM is estimated to be 13–22 times higher than in the general population and additionally increases to 38-fold in FAAMM subjects with *CDKN2A* mutations [100,101]. Interestingly, nearly 90% of sporadic PDAC harbour alterations in CDKN2 [49].

6.3. Lynch Syndrome

Lynch syndrome, also known as hereditary non polyposis colorectal cancer, is an autosomal dominant disease associated with an increased predisposition to colorectal, gastric and endometrial cancers [102]. LS is caused by germline mutations in mismatch repair genes (MMR), including genes encoding DNA reparation proteins: *MLH1*, *MSH2*, *MSH6*, *PMS2* and *EPCAM* gene, which lead to epigenetic silencing of *MSH2* [103]. The malfunctioning variants are referred to as *path_MLH1*, *path_MSH2*, *path_MSH6* and *path_PMS2* [104]. Mutations in the *MLH1* and *MSH2* genes have a greater impact on DNA repair; therefore, patients carrying these mutations have a significantly higher risk of developing cancer compared to patients with *MSH6* or *PMS2* mutations [103,105]. Kastrinos et al. demonstrated that patients from families with germline *MMR* gene mutations have a cumulative risk of pancreatic cancer ranging from 1.31% up to the age of 50 years to 3.68% up to age of 70 years [68]. This represents an 8.6-fold increase compared with the general population [68]. Similar results of the cumulative incidence of PC for *path_MMR* variants carriers were reported by Møller et al., who estimated a cumulative risk of 1.1% up to age 50, 3.9% up to 70 and 6.2% up to 75 years of age [88].

6.4. Peutz–Jeghers Syndrome

Peutz–Jeghers syndrome is a rare autosomal dominant disorder. PJS is most often caused by a germline mutation in the serine/threonine kinase 11 or liver kinase B1 STK11/LKB1 genes on chromosome 19p13.3 [106]. The *STK11/LKB1* is a tumour suppressor gene that plays an important role in regulating the cell cycle [107]. Mutations in *STK11* are identified in 50% to 80% of families with PJS. In other patients, PJS is probably the cause of de novo mutations [108]. It is characterised by hamartomatous gastrointestinal polyps and pigmented cutaneous and mucocutaneous macules [108]. Individuals with Peutz–Jeghers syndrome have an increased risk for developing colorectal, gastric system, breast, uterine, cervical, lung, ovarian, testicular and pancreatic cancers [109]. The literature has reported that the cumulative risk of developing PC ranges from 11 to 36% at the age of 70 years, which presents a 136-fold increase compared with the general population [61,78].

6.5. Li–Fraumeni Syndrome

Li–Fraumeni syndrome is a rare hereditary autosomal dominant disorder due to germline pathogenic or likely pathogenic variants in the *TP53* gene. Approximately 7% to 20% of patients with germline *TP53* pathogenic variants have mutations derived de novo. LFS is characterised by the development of a wide spectrum of childhood and adult-onset malignancies. The main cancers are adrenocortical carcinomas, breast cancer, central nervous system tumours, osteosarcomas and soft-tissue sarcomas [110]. The lifetime risk of cancer in individuals with LFS approaches 75% in males and almost 100% in females [110,111]. LFS is also associated with an increased risk of several additional cancers, including leukaemia, lymphoma, gastrointestinal cancers, cancers of head and neck, kidney, skin, lung, larynx, ovary, thyroid, prostate, testis and pancreas. In addition to these cancers, patients with LFS have a 7.3-fold increased risk of PDAC [65].

Pobrano z / Downloaded from Repository of Wrocaw University of Environmental and Life Sciences 2025-10-15 21:43

6.6. Familial Adenomatous Polyposis

Familial adenomatous polyposis syndrome is an autosomal dominant disease, predominantly caused by a germline mutation in the adenomatous polyposis coli *(APC*) gene on chromosome 5q21 [112]. It is a disease of high penetrance and variable expression [86]. Approximately 20–30% of FAP cases arise from de novo mutations, without a family history [113]. The mutation site in the *APC* gene determines the progression, clinical phenotypic variations (including Gardner and Turcot syndromes) and the risk of development of extracolonic manifestations of the disease [112,114]. FAP is characterised by hundreds to thousands of adenomatous polyps of the gastrointestinal mucosa [115]. FAP is also correlated with the incidence of other malignancies, mainly colorectal cancer, gastric, duodenal, hepatoblastoma and desmoid tumours [116]. The lifetime incidence of pancreatic cancer in patients with FAP is relatively low. The lifetime risk has been estimated at around 2%, but it is still four times higher than in the general population [69,87]. Furthermore, reports on the genetic link between the two disorders are limited and remain inconclusive. Hori et al. demonstrated sporadic *APC* mutations in pancreatic cancer [117], which has not been confirmed in other studies [118]. Another group of investigators hypothesised that *APC* mutation may play a role in the initiation of pancreatic cancer [119].

6.7. Ataxia–Telangiectasia

Ataxia–telangiectasia is an autosomal recessive disorder characterised by neurological symptoms, such as cerebellar atrophy with progressive ataxia, and a marked predisposition to cancer [120]. Ataxia telangiectasia is due to mutations of the ATM gene, whose product is involved in DNA double-break repair [121]. In a study of 166 familial pancreatic cancer probands, 2.4% were carriers of the deleterious *ATM* variant [120]. Large-scale sequencing-based studies have identified up to 18% of *ATM* mutations in some cohorts of patients with pancreatic ductal adenocarcinoma [122–124]. The risk of pancreatic cancer among *ATM* pathogenic variant carriers has been estimated at 6.3% by age 70 (Table 2) [125].

6.8. Fanconi Anaemia

Fanconi anaemia is characterised by bone marrow failure, developmental abnormalities and an increased risk to develop malignancies. FA is a predominantly autosomal recessive disease. Nineteen FA-related genes (FANC) whose products suppress interstrand crosslink sensitivity have been described. FA patients harbour biallelic mutations in a particular FA gene, with the exceptions of *FANCB (*X-linked) and *FANCR*/*RAD51,* which are autosomal dominant [126]. Mutations in most FA genes lead to a chromosomal instability disorder. Several studies have reported FA gene mutations in pancreatic cancers [127–130]. Roberts et al. reported protein-truncating variants of AF (*BRCA2, PALB2, FANC, FANCG* and *FANCM*) in individuals with familial pancreatic cancer [84]. In another study, Rogers et al. showed that germline and somatic mutations in *FANCC* and *FANCG* may contribute to pancreatic cancer [128]. Mutations in the *FANCC* gene have been detected in two young-onset pancreatic cases, but none in *FANCG* [131].

6.9. Multiple Endocrine Neoplasia Type 1

Multiple endocrine neoplasia type 1 is a rare autosomal dominant and hereditary endocrine tumour syndrome with high penetrance. Familial MEN1is characterised by the combined occurrence of tumours of the parathyroid glands, endocrine pancreas, duodenum, anterior pituitary and, less commonly, of the stomach, adrenal gland, thymus and lungs [132]. MEN1 is caused by several germline mutations in the tumour suppressor *MEN1* gene that encodes the protein menin [133]. In a study by Ito et al. in patients with pNETs, *MEN-1* was detected in 10% of patients [134]. On the other hand, pancreatic endocrine tumours occur in 40–70% of MEN-1 patients [135]. MEN-1-associated pancreatic

Pobrano z / Downloaded from Repository of Wrocaw University of Environmental and Life Sciences 2025-10-15 21:43

Pobrano z / Downloaded from Repository of Wrocaw University of Environmental and Life Sciences 2025-10-15 21:43

endocrine tumours are most commonly gastrinomas and non-functioning tumours [136]. Pancreatic endocrine tumours are the leading cause of death in MEN-1 patients [137].

6.10. Von Hippel–Lindau Syndrome

Von Hippel–Lindau syndrome is a hereditary autosomal dominant disease caused by mutations in the *VHL* gene located on chromosome 3. It is a disease with high penetration, early onset and a high prevalence of clinical symptoms. VHL is characterised by multi-organ tumours of the central nervous system, kidney, adrenal and reproductive organs and pancreas. The most common type of tumour in VHL is hemangioblastoma. Renal cell carcinoma (RCC) and endolymphatic and pancreatic neuroendocrine tumours are also diagnosed in individuals with VHL [64,138]. Approximately 35–70% of patients with VHL have pancreatic lesions, and 5–17% develop neuroendocrine tumours [82,139]. In a study by Hammel et al., pancreatic disorders were found in 77% of patients with VHL. This included true cysts (91.1%), serous cystadenomas (12.3%), neuroendocrine tumours (12.3%) or combined lesions (11.5%). Interestingly, in 7.6% of patients, the pancreas was the only organ affected [140]. Reich et al. reported an age-dependent cumulative probability of pancreatic neuroendocrine neoplasm of 10 % up to 40 and 26% up to 60 years of age [141].

6.11. Neurofibromatosis 1

Neurofibromatosis 1, also known as von Recklinghausen disease, is an autosomal dominant disorder characterised mainly by neurocutaneous manifestations [142]. It is caused by a mutation in the *NF-1* gene, which encodes the neurofibromin protein, leading to uncontrolled cell proliferation and the development of some tumours [143]. Gastrointestinal involvement is rare but is associated with a significant risk of malignancy. To date, there are only a few case reports linking NF-1 to pancreatic neuroendocrine tumours [70,144,145].

6.12. Tuberous Sclerosis (Bourneville's Disease)

Tuberous sclerosis is an autosomal dominant neurocutaneous multisystem disorder. The disease is due to mutations in one of two genes—*TSC1* located on chromosome 9q34 encoding for the protein hamartin, or *TSC2* located on chromosome 16p13.3 encoding for the protein tuberin [146,147]. Among familial cases of TSC, about half show an association with the *TSC1* gene and half with the *TSC2* gene [148]. Pancreatic endocrine tumours have been reported in a small percentage of patients with TSC [149–151].

As presented above, most of the studies provide evidence for the contribution of genetic background in the development of cancer syndromes and related PC. Considering this evidence, it seems reasonable to include individuals with cancer syndrome in screening. The aim of these screenings would be to identify pre-cancerous lesions, which would enable actions to be taken to prevent the development of cancer or to detect cancer at an early, still treatable stage.

7. Targeted Therapy Overview and Future Perspectives

Though immunotherapy, microbiological therapy and targeted therapy (examples in Table 3 below) remain the most promising treatment options for pancreatic cancer at the moment, we should not forget about traditional methods, such as surgery (often combined with neoadjuvant therapy), radiation and chemotherapy (including adjuvant therapy) [152,153]. Further, palliative care plays an important role in many PC cases, as this is still a tumour with a high mortality rate [153]. Chemotherapy of pancreatic cancer depends on the stage and previous/planned treatment; MFOLFIRINOX (modified leucovorin, 5-fluorouracil, irinotecan, oxaliplatin) or gemcitabine with capecitabine are often used for 6 months after radical resection [153]. There is currently no immunotherapy approved for PC treatment, as it is considered to be a less immunogenic cancer; however, it

Pobrano z / Downloaded from Repository of Wrocaw University of Environmental and Life Sciences 2025-10-15 21:43

may be used in combination with chemotherapy, chemoradiotherapy, vaccines and cytokine antagonism [153]. In recent years, research on modern therapies is becoming more and more extensive, and it is probable that new methods will be combined with traditional methods of treating PC [152,153].

When it comes to developing new therapies, there is hope in organoid models that can simulate the characteristics of pancreatic tumours [154]. This is a rapidly evolving preclinical model that allows for studying the characteristics of pancreatic cancer and leads to an improvement in patient outcomes [154].

Currently, the standards for first-line treatment in PDAC are FFX and GnP regimens. Unfortunately, in most cases, first-line therapy is not successful, but there are still not enough RTCs. It is suggested that FFX followed by GnP or GnP followed by FFX is the most feasible or beneficial approach [155]. The high incidence of germline mutations in PDAC patients makes targeted therapy tempting [155].

Given the frequent instability of the genome, which refers to a range of genetic alterations, from point mutations to chromosomal rearrangements caused by damage to the DNA repair mechanisms, various interventions to accumulate double-strand breaks and to induce apoptosis have been investigated in pancreatic tumours, the most effective of which is treating patients with inhibitors of poly-(adenosine diphosphate ribose) polymerase (PARPi for short) [156,157]. The European Medicines Agency registration allows for the administration of PARPi as a maintenance therapy in patients with pancreatic cancer, in whom a germinal mutation in *BRCA1/2* was detected, and disease progression was not observed for a minimum of 16 weeks after first-line treatment with platinum therapy. Olaparib has been also investigated in clinical trials as a monotherapy [29]. Olaparib proved to be an effective maintenance therapy for BRCA germline patients and prolonged progression-free survival [29]. There are numerous indications that it is possible, after advanced genetic testing, to expand the group of patients receiving PARPi [158]. The results of clinical trials in ovarian cancer, in which PARPi have been used for a long time, demonstrated the effectiveness of PARPi also in patients with somatic changes in the *BRCA1/2* genes, as well as with characteristic changes in the genome associated with HRD or referred to as genomic instability. Moreover, the latest registration of PARPi, called Niraparib, assumes that this drug is administered to patients with ovarian tumours, regardless of their mutational status [158].

With the development and rising accessibility of the omics diagnostic methods and data analysis, we can better characterise the genetics of pancreatic cancer, although the relevance of genetic markers and signatures still needs to be understood [159,160]. High-throughput methods have revealed other non-germline genetic variants involved in PDAC pathogenesis. The in silico analysis of expression data has revealed new therapeutic perspectives, such as bleomycin, as potential therapeutic agents for PDAC [161], although other non-DNA biomarkers can characterise PDAC on the molecular level and the response to therapy [162]. Although the NTRK pathogenic variant is rare with PDAC, such tumours can be treated with larotrectinib [163], and first reports on such cases have been published [164].

Due to the short life expectancy of patients and the time-consuming nature of such analyses, there have been few studies to date extending the indication for the administration of PARPi in pancreatic cancer.

Precision medicine is very promising for the treatment and early diagnosis of pancreatic cancer. It is also worth mentioning that there are three types of new-generation treatments for pancreatic cancer-associated mutations: nucleic acid drugs, small molecules and antibodies. Nucleic acid therapy has many advantages over traditional drugs, for example: the inhibition of previously inaccessible targets, faster and longer lasting responses than protein inhibition, less severe side effects and short development duration [165]. Since 90% of pancreatic cancers have a KRAS mutation, it is the most common target. Anti-tumour activity was detected in mice bearing this mutation. It was also tested in more than 1000 clinical trials, and few ASOs showed positive results. In addition, ASO targeting XIAP combined with gemcitabine showed some effect. Fifty-eight percent of patients that received this combination lived 6 months or longer [165].

There is no approved RNAi treatment for pancreatic cancer, although in clinical trials, Golan et al. targeted the most common gene—KRAS. Unfortunately, the clinical trials did not show promising results—in 83% of patients, no change accrued, and in 17%, there was very little effect, but the treatment is safe [165]. It can be implemented in combination with chemotherapy. Nishimura et al. presented a trial in which a fine-needle injection of RNA oligonucleotide-targeted CHST15 turned out to be safe [166]. Although there are many kinds of nucleic acid drugs, such as small interfering RNA, decoys, CpG oligodeoxynucleotides, microRNA, decoys and aptamers, which are very promising, unfortunately, only 30% of patients' mutations can be treated with drugs, because it is very hard to inhibit targeted RNA in humans: *PALB2*, *ATM*, *HER2*, *MET*, *MLH1*, *MSH2*, *MSH6*, *PMS2*, *KRAS*, *BRCA1 and 2*, *PI3CA*, *PTEN*, *CDKN2A*, *BRAF* and *FGFR1* [167].

Table 3. Targeted therapies currently used and in clinical trials among pancreatic cancer patients.

Treatment	Gene and Indication	Side Effects	References
PARPi (e.g., Niraparib, Olaparib)	*BRCA1/2*—known or suspected BRCA gene mutation, no worsening after the treatment with platinum resistant agent; also targeting tumours with HRD, including mutations in: *PALB2, RAD51C, BRCA 1/2*	nausea, vomiting, diarrhoea or constipation, fatigue, anaemia, leukaemia, taste changes	[23,30,157–159]
Erlotinib	*EGFR*—advanced pancreatic cancer may be administered in combination with gemcitabine	neutropenia, febrile neutropenia, fatigue, nausea, infections, vomiting, mucositis	[168–170]
Larotrectinib and entrectinib	*NTRK*—pancreatic cancer with NTRK mutations, resistance to other treatment	fatigue, nausea, vomiting, constipation, weight gain, and diarrhoea	[163,164]
Everolimus	inhibitor of mammalian target of rapamycin (mTOR); mutations in TSC1 and TSC2 genes	stomatitis, infections, diarrhoea, peripheral edema, fatigue rash, anaemia, hypercholesterolemia, lymphopenia, elevated aspartate transaminase (AST), fasting hyperglycemia	[171]
Belzutifan	hypoxia-inducible factor-2 alpha (HIF-2α) inhibitor, used for the treatment of von Hippel–Lindau disease-associated cancers	anaemia, low oxygen levels—shortness of breath, headache, dizziness, tiredness; nausea; increased blood sugar (increased thirst or urination, dry mouth, fruity breath), abnormal kidney function tests	[172–175]
Palbociclib	*CDKN2A mutations*	nausea, diarrhoea, vomiting, decreased appetite, changes in taste, tiredness, numbness or tingling in	[176]

Pobrano z / Downloaded from Repository of Wrocaw University of Environmental and Life Sciences 2025-10-15 21:43

		arms, hands, legs, and feet, sores on the lips, mouth or throat	
[experimental/clinical trials]	*TGFBR2*—known or suspected *TGFBR2* gene mutation or its pathway	unknown	[19–21,177,178]
[experimental/clinical trials]	*SMAD4 mutations*	unknown	[179–181]
[experimental/clinical trials]	*MLL3 mutations*	unknown	[182–185]

8. Drug Resistance Induced by Genetic and Genomic Alterations

Designing effective treatment regimens requires an understanding of all potential mechanisms of therapeutic resistance. Genetic and epigenetic changes in tumour cells may play a significant role in resistance to chemotherapy, radiotherapy and immunotherapy for PC.

Among the genetic alterations contributing to drug resistance, mutations in the tumour suppressor genes *TP53*, *SMAD4* and *CDKN2A,* and especially mutations in the KRAS oncogene, have been highlighted [19,186]. In pancreatic cancer, KRAS is the most frequently mutated oncogene [187]. The activation of mutations in KRAS, observed in more than 90 % of pancreatic ductal adenocarcinoma cases, are a critical factor involved in tumour initiation and progression. Studies have shown a positive correlation of KRAS with gemcitabine resistance [188]. Although the first therapies based on KRAS inhibitors have been introduced, they may only benefit a small group of patients. Sotorasib, adagrasib and other currently tested inhibitors mainly target the *KRAS* G12C mutation, and there are no approved drugs targeting KRAS G12D and G12V [189,190].

In addition, drug resistance may be acquired during therapy and may result from genetic mutations arising during the treatment process as well as adaptive mechanisms and natural clonal selection of tumour cells [191]. Among patients treated with KRAS G12C inhibitors, the resistance mechanism was detected in 45% of patients. Acquired KRAS gene alterations associated with the observed resistance to treatment included G12D/R/V/W, G13D, Q61H, R68S, H95D/Q/R, Y96C and amplifications in *KRAS* [192]. It is thought that secondary mutations may lead to an increase in the active KRAS protein bound to GTP and also prevent binding to the drug [193]. Awad et al. observed resistance to both adagrasib and sotarisib associated with R68S and Y96C mutations, and H95D, H95Q and H95R mutations resulted in resistance to adagrasib only. Interestingly, in patients with acquired resistance to adagrasib, additional pathogenic alterations occurring not in the *KRAS* gene itself, but they were identified in the RTK-RAS signalling pathways. These included mutations in the *NRAS*, *BRAF*, *MAP2K1*, *RET*, *NF1* and *PTEN* genes, and they also played a significant role in the development of treatment resistance [192]. Another aspect is resistance to radiotherapy, which has been found for mutations in *KRAS*, *TP53* and *CDKN2A* [194].

The occurrence of resistance may also result from epigenetic changes, such as the regulation of gene expression by small non-coding RNAs (miRNAs). The results from studies have shown that the expression of specific miRNAs in PC correlates with sensitivity or resistance to chemotherapy [195,196]. Gemcitabine-resistant cells were characterised by low expression levels of miR-101-3p and miRNA-124 [197,198]. Furthermore, gemcitabine treatment led to secondary changes in the levels of individual miRNAs (miRNA-17-5p, miRNA-21, miRNA-203), consequently leading to chemoresistance [199–201].

9. Conclusions

Advances in sequencing technology are now reducing the time needed to obtain results and opening new opportunities for patients. Moreover, advanced genomic testing also provides information on potential susceptibility to other available targeted therapies, giving patients the chance to receive effective treatment. The current state of knowledge regarding the genetics of pancreatic cancer and the emerging new possibilities of available treatment options reflects advances in genomic medicine and personalised medicine, providing new hopes for the near future.

Genome-wide association study of glioma subtypes identifies specific differences in genetic susceptibility to glioblastoma and non-glioblastoma tumors

A full list of authors and affiliations appears at the end of the article.

Abstract

Genome-wide association studies (GWAS) have transformed our understanding of glioma susceptibility, but individual studies have had limited power to identify risk loci. We performed a meta-analysis of existing GWAS and two new GWAS, which totaled 12,496 cases and 18,190 controls. We identified five new loci for glioblastoma (GBM) at 1p31.3 (rs12752552; $P = 2.04 \times 10^{-9}$, odds ratio (OR) = 1.22), 11q14.1 (rs11233250; $P = 9.95 \times 10^{-10}$, OR = 1.24), 16p13.3 (rs2562152; $P = 1.93 \times 10^{-8}$, OR = 1.21), 16q12.1 (rs10852606; $P = 1.29 \times 10^{-11}$, OR = 1.18) and 22q13.1 (rs2235573; $P = 1.76 \times 10^{-10}$, OR = 1.15), as well as eight loci for non-GBM tumors at 1q32.1 (rs4252707; $P = 3.34 \times 10^{-9}$, OR = 1.19), 1q44 (rs12076373; $P = 2.63 \times 10^{-10}$, OR = 1.23), 2q33.3 (rs7572263; $P = 2.18 \times 10^{-10}$, OR = 1.20), 3p14.1 (rs11706832; $P = 7.66 \times 10^{-9}$, OR = 1.15), 10q24.33 (rs11598018; $P = 3.39 \times 10^{-8}$, OR = 1.14), 11q21 (rs7107785; $P = 3.87 \times 10^{-10}$, OR = 1.16), 14q12 (rs10131032; $P = 5.07 \times 10^{-11}$, OR = 1.33) and 16p13.3 (rs3751667; $P = 2.61 \times 10^{-9}$, OR = 1.18). These data substantiate that genetic susceptibility to GBM and non-GBM tumors are highly distinct, which likely reflects different etiology.

AUTHOR CONTRIBUTIONS

M.L.B., B.S.M., R.S.H. and J.S.B.-S. managed the project; R.S.H., M.L.B., B.S.M., J.S.B.-S., R.B.J., Q.T.O., B.K. and M.R.W. drafted the manuscript; Q.T.O., K.L., B.K., J.E.E.-P. and P.A.D. performed statistical analyses; Y.C., K.L., Y.L. and B.K. performed bioinformatics analyses; B.S.M., J.S.B.-S., M.R.W., J.K.W., C.J., D.I., R.K.L., G.A., P.A.D., U.A., T.R., H.H., L.M., M.L.K., H.S., J.L.B., F.D., D.L, C.I.A, C.L., R.T.M., J. Shildkraut, F.A.-O., S. Sadetski, M. Scheurer, S. Shete, E.B.C., S.H.O., R.B.J., R.S.H. and M.L.B. developed the GICC protocol and performed sample acquisition; and P.R., S.C., M. Linet, Z.W. and M.Y. provided the National Cancer Institute (NCI) data. In the UK, P.B., A.S., M.J.S., S.J.F. and R.S.H. developed patient recruitment, performed sample acquisition and performed sample collection of cases; P.B. oversaw DNA isolation and storage, and performed case and control ascertainment, and supervision of DNA extractions. In Germany, M. Simon, M.M.N., H.-E.W., S. Schreiber and J. Schramm developed patient recruitment, and oversaw performed blood sample collection; M. Simon oversaw DNA isolation and storage and performed case and control ascertainment, and supervision of DNA extractions; and S. Herms, S. Heilmann and K.G. performed experimental work. In France, M. Sanson and J.-Y.D. developed patient recruitment; M. Labussière, A.-L.D.S., P.G., K.M., A.I. and K.H.-X. performed patient ascertainment. M. Lathrop performed laboratory management and oversaw genotyping of the French samples. All authors contributed to the final manuscript.

Glioma accounts for around 27% of all primary brain tumors and is responsible for approximately 13,000 cancer-related deaths in the United States each year[1, 2]. Gliomas can be broadly classified into GBM and lower-grade non-GBM tumors[3]. Gliomas typically have a poor prognosis irrespective of medical care, with the most common form, GBM, having a five-year survival rate of only 5% (ref. 4).

So far, no environmental exposures have been robustly linked to the risk of developing glioma, except for moderate to high doses of ionizing radiation, which accounts for a small proportion of cases[5]. Evidence for an inherited predisposition to glioma is provided by a number of rare inherited cancer syndromes, such as Turcot's and Li–Fraumeni syndromes, as well as neurofibromatosis. Even collec-tively, however, these account for little of the twofold familial risk of glioma[6]. Our understanding of the heritability of glioma has been transformed by recent GWAS, which have identified single-nucleotide polymorphisms (SNPs) at 13 loci influencing risk[7–14].

Previous individual studies have had limited statistical power for the additional discovery of new glioma risk loci[15]. Therefore, to gain more comprehensive insight into glioma etiology, we performed a meta-analysis of previously published GWAS and two new GWAS, which allowed us to identify 13 new risk loci for glioma.
